The test to determine whether a witness is qualified as an expert is to inquire whether his knowledge of the matter in relation to which his opinion is asked is such that it will probably aid the trier of the question to determine the truth.

With respect to the competence of the coroner to testify as an expert witness, the Supreme Court called attention to the fact that he had taken a regular three months undertakers course at the University of Minnesota. Sixty hours of that course was devoted to the study of death causes. His instructor had been a physician of the regular staff of the university, from whom he had received instruction relative to symptoms of carbon monoxide deaths. The witness had pursued the business of undertaker since 1922 and during that time had taken care of and prepared for burial some 600 bodies. As coroner, he examined minutely the bodies of those who had died a sudden or violent death. The witness testified as to the observation he had made of the body and surrounding conditions. He carried the body to his place of business, undressed it, examined it closely, and embalmed it within two hours. In so doing, he paid particular attention to the color of the surface tissue, to the color of the blood, and noticed that it did not coagulate. The witness, concluded the Supreme Court, was qualified to aid the jury as to the cause of death, and the trial court committed no error in permitting him to testify. No other error having been found in the case, the Supreme Court affirmed the judgment of the trial court for the defendant company.—*Palmer v. Order of United Commercial Travelers of America (Minn.)*, 253 N. W. 543.

Malpractice: Joint Liability of Physicians; Hypothetical Question Based on Hospital Record.—The appellee, Viola Petry, sued the appellants, physicians and surgeons, alleging that the death of her husband was attributable to their joint negligence. The trial court gave judgment against the physicians and they appealed to the court of appeals of Ohio, Stark County.

On January 18, the husband of the appellee became ill, suffering from a duodenal ulcer. Dr. K. E. Reighard, who was called to take care of him, had the patient removed to a hospital, where Dr. L. F. Mutschman was called in consultation. Thereafter the two physicians concluded that a bridge, anchored on a single tooth, should be removed and a dentist was called to do the extraction. The socket bled profusely, and the dentist packed it with gauze. Twenty-four hours thereafter the packing was removed and the socket repacked. The gauze removed was foul smelling. At midnight, January 22, the nurse in charge of the patient made notation on the hospital record that the patient manifested occasional jerking or muscular twitching and hypersensitiveness to noises. On the following morning, January 23, a gastro-enterostomy was performed by Dr. Mutschman, assisted by Dr. Reighard. No immediate change was noted in the patient's condition. In the evening of January 25, however, the patient died of a tetanus infection, the source of which was located in the tooth's socket.

The appellee, the patient's wife, contended that the physicians were jointly negligent in not discovering the presence of tetanus, in their failure to use ordinary care in its treatment, and in performing the operation when the patient's condition was so precarious and chances of recovery so remote. It was not contended that the operation was unskillfully done, but that it destroyed the patient's resistance, hastened and directly contributed to his death, and was therefore the proximate cause. The physicians, on the other hand, argued that they were not joint tortfeasors or partners. They denied that either was an employee of the other and contended that they must be considered as independent agents, without concert of action, collusion or common design, and that each was responsible only for his own negligence, and nothing more.

In *Village of Mineral City v. Gilbow*, 81 Ohio St. 263, 90 N. E. 800, 25 L. R. A. (N. S.) 627, it was stated:

If there is no concert of action—no common intent—there is no joint liability. . . . But a different principle applies where the injury is the result of a neglect to perform a common duty resting on two or more persons, although there may be no concert of action between them.

In the present case, said the court of appeals, Dr. Reighard recommended and procured Dr. Mutschman. Each had an equal opportunity to diagnose the patient's ailment and to prescribe a remedy. Each consulted with the other, and each advised the operation. Each was present at the time of the operation, one operating, the other assisting. Each participated in and approved of all that was done. There was, therefore, a concert of action and a common purpose and design. A joint action, concluded the court, was therefore maintainable against the physicians.

Hospital records, properly identified, are admissible in evidence. The opinions of expert witnesses in response to hypothetical questions based solely on the facts disclosed by such records are also admissible, even though the facts are not repeated in the questions. The trial court correctly refused to instruct the jury that the skill and care of the appellant physicians were to be judged by that possessed and exercised by "physicians and surgeons practicing medicine and surgery in the city of Alliance or vicinity." The words "in the city of Alliance or vicinity," said the court, improperly limit and confine the degree of care resting on the appellants. The correct rule was laid down in *Whitesell v. Hill*, 101 Iowa, 629, 70 N. W. 750, 37 L. R. A. 830, as follows:

The degree of knowledge, care, and skill required of a physician or surgeon is that which is ordinarily possessed by those practicing in similar localities, and is not necessarily limited to that which is in fact exercised in his particular locality.

And in *Gramm v. Boener*, 56 Ind. 497, as follows:

It will not do, as we think, to say, that if a surgeon or physician has exercised such a degree of skill as is ordinarily exercised in the particular locality in which he practises, it will be sufficient. There might be but few practising in the given locality, all of whom might be quacks, ignorant pretenders to knowledge not possessed by them, and it would not do to say, that, because one possessed and exercised as much skill as the others, he would not be chargeable with the want of reasonable skill.

After considering all the assignments, the court of appeals could find no prejudicial error and consequently affirmed the judgment of the trial court.—*Mutschman et al. v. Petry (Ohio)*, 189 N. E. 658.

COMING MEETINGS

- Medical and Surgical Association of the Southwest, El Paso, Texas, Nov. 22-24. Dr. W. Warner Watkins, Box 1587, Phoenix, Ariz., Secretary.
- Pacific Coast Society of Obstetrics and Gynecology, Oakland and Del Monte, Calif., November 21-23. Dr. Clarence A. De Puy, 230 Grand Avenue, Oakland, Secretary.
- Puerto Rico, Medical Association of, Santurce, Dec. 14-16. Dr. Julio R. Rolenson, Box 3403, Santurce, Secretary.
- Radiological Society of North America, Memphis, Tenn., December 3-7. Dr. Donald S. Childs, 607 Medical Arts Building, Syracuse, N. Y., Secretary.
- Southern Surgical Association, Sea Island, Ga., Dec. 11-13. Dr. Robert L. Payne, 142 York Street, Norfolk, Va., Secretary.
- Western Surgical Association, St. Louis, December 7-8. Dr. Albert H. Montgomery, 122 South Michigan Boulevard, Chicago, Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Metastasis in Squamous Carcinoma.—Price correlates the results of pathologic investigations with the available clinical data to determine why secondary deposits develop in one case of squamous carcinoma and are absent in another clinically similar case. The evidence indicates that there is no correlation between the clinical condition of the patient and the development of distant metastases. There is no constant relationship between the site of the primary tumor and the site of the distant metastases. The commonest sites for metastases in the series were thirteen cases in the lungs, seven in the liver and five in the kidneys. Less frequently metastases were formed in other sites. From a wider consideration of the development of metastases from numerous primary tumors of various types, the only consistent feature that emerges is that tumors arising in certain primary sites have a tendency to form metastases in certain tissues of predilection. There is a peculiar relationship between the site of the primary tumor and the site of the secondary deposits.

Vaginal Fistulas in Carcinoma of Cervix.—Smith studied the records of 2,852 patients, proved by biopsy to have carcinoma of the cervix and who had received radiation treatment, to determine the incidence of vaginal fistula following this form of therapy. The changes of the technic of radiation therapy are significant in view of the parallel yearly incidence of fistula. From 1922 to 1925 the limitation of unfiltered glass radon seeds to selected cases and the substitution of low voltage roentgen therapy for the external application of radium was accompanied by a decrease in the incidence of fistula as compared to preceding years. With the substitution of gold radon seeds, and with high voltage roentgen therapy replacing the low voltage type, the incidence of fistula was again at a comparatively high level in 1926 to 1928. In 1929 to 1932, with gold seeds omitted from all primary treatments and with

roentgen therapy preceding the radium therapy, the incidence of fistula remained consistently low. In 1921, the peak of the era of unfiltered radon seed therapy, the incidence of fistula and the percentage of patients treated with seeds reached the highest levels. Of those patients treated in the years preceding 1926 and who developed fistula there was only one alive in 1933, although several had lived two, three and four years. It seems fair to assume that the advancement of the disease before treatment plays a large part in the incidence of fistula. The yearly incidence in patients now dead parallels closely the yearly incidence in all irradiated patients. A high incidence of fistula is shown in primary carcinoma of the cervical stump. Each patient in this group had a supracervical hysterectomy, for some cause other than carcinoma of the cervix, at least four years before the onset of the symptoms of carcinoma. In the group of primary carcinoma of the cervical stump the incidence approximates that of the recurrent group, suggesting that hysterectomy increases the incidence of fistula, whether performed years before for other reasons or as the initial therapy for cervical carcinoma. The high percentage of fistula patients receiving retreatment in contrast to the relatively small percentage of total patients receiving retreatment indicates the increase in the incidence of the fistula in retreated patients. A comparison of the incidence of fistula in structural types with the type distribution of all cases shows the incidence in the adult type of growth to be only half as high as in the plexiform or in the anaplastic type. This may be due to the relative radioresistance of the adult type. A comparison of the incidence between irradiated and untreated patients shows that fistulas occur at least twice as frequently in untreated as in irradiated patients.

Treatment of Hookworm Anemia.—Rhoads and his associates made studies on eighty-three patients, including children and adults, having anemia and hookworm infection. The patients were selected primarily because they had less than 50 per cent of the normal hemoglobin, had no complicating conditions and had hookworm ova in the stools. Field observations were carried out on thirty-two patients. Hospital patients were maintained on a basal diet resembling closely the usual food of the Puerto Rican peasants. Particular attention was given to the nature of the relationship of the hookworm to the anemia. The relative effectiveness of treatment

of the anemia by removal of the parasites, by improvement of the diet and by the administration of iron or liver extracts was determined. Hematopoietic effects were judged by daily observations of the course taken by the reticulocytes and by determinations of the red blood cell and hemoglobin values of the venous blood on alternate days or at appropriately longer intervals. In the field observations the red blood cell and hemoglobin values were determined from capillary blood at approximately weekly intervals. The study revealed that: 1. The hypochromic anemia of hookworm disease in Puerto Rico is apparently caused by a combination of blood loss, dietary deficiency and gastro-intestinal changes probably resulting from defective nutrition. 2. The removal of the hookworms without other therapy had little effect on anemia or clinical condition. 3. The administration of large doses of iron, with or without the removal of the hookworms, produced rapid improvement of blood values and clinical conditions. 4. The advantages of direct treatment of the anemia with iron are indicated.

Iodine Tolerance Test for Iodine Content of Blood.—

For the quantitative estimation of iodine in the blood, Perkin and his collaborators collected 10 cc. of whole blood in a nickel crucible and combusted it with potassium carbonate at 500 F. in a muffle furnace for five hours. The ash was extracted with alcohol and filtered, and the filtrate was evaporated to dryness. The residue from the filtrate was taken up with water and made slightly acid, and the iodide was oxidized to iodate. In forty normal subjects the iodine content was found to vary between 0.00024 and 0.00185 mg. to each 10 Gm. of whole blood. In thirty-nine patients with suspected hyperthyroidism the range for the group was between 0.00072 and 0.0141 mg. of iodine to each 10 Gm. of whole blood. The authors observed that following the oral administration of compound solution of iodine the blood iodine level was increased considerably, varying with the time the blood was taken. This led them to investigate in normal persons the relation of the iodine concentration of the blood with respect to time, following the ingestion of a known amount of iodine. A test was outlined as follows: After a 10 cc. sample of blood had been obtained, 10 minims (0.6 cc.) of compound solution of iodine in milk was given by mouth in the morning, breakfast being limited to one cup of coffee and a piece of toast. Five blood samples were withdrawn at one-half, one, one and one-half, two and one-half and seven hour periods and the total iodine was estimated. The amount of blood taken was reduced to 3 cc., since the iodine concentration was increased from five to fifteen times the normal. During the day normal meals were taken, with the exception that no foods high in iodine content were allowed. Total iodine estimations were made on the urine collected during the twenty-four hour

period. Since an abnormal iodine metabolism is considered to exist in persons with hyperthyroidism, the same procedure was used in patients with suspected hyperthyroidism. Analysis shows that the blood iodine concentration did not increase to as high a level in patients with a clinical and histologic picture of hyperthyroidism as in normal subjects. The hyperthyroid curves fall below, while the normal curves rise above the hypothetical line of 10 micrograms. Such a finding might be accounted for on the grounds that a hyperplastic thyroid may have a greater affinity for iodine than a resting gland and thus leave less iodine in the blood stream. However, it may be that there is an increased metabolism of iodine in the hyperthyroid patient, although the amount of iodine excreted in the urine in these cases, in comparison with the normal, would not confirm such a hypothesis. The results indicate that estimating the blood iodine concentration at definite intervals, following the ingestion of a single dose of compound solution of iodine, may be a valuable guide in the diagnosis of hyperthyroidism.

Method for Determining Serum Phosphatase.—King and Armstrong describe a method for estimating serum phosphatase activity in which the enzyme is allowed to act on phenyl phosphate and the liberated phenol is determined. The method is adaptable for use with bile. The time required for duplicate analysis of a serum is about one hour. The accuracy of the method is considered to be as great as or greater than that of previously described methods. The authors believe that the incubation period of thirty minutes as used in their method is of advantage in that it gives results which more truly represent the actual enzyme content of the blood than is the case with methods requiring a longer period of incubation. Theoretically, a proper measurement of the amount of the enzyme should be based on the initial velocity of hydrolysis. While the attainment of this condition is not practicable in a clinical method, the shortening of the period of hydrolysis, without any sacrifice in the accuracy of the analytic procedures, should make for the attainment of more exact and hence more significant values. When large numbers of serums are being examined as a routine, the authors have found duplicate analyses to agree on the average to within 5 per cent for those values lying within the normal range. For the higher values the percentage of error is correspondingly less. A number of serums that they examined simultaneously by their own method and by that of Jenner and Kay agreed closely. Most of the differences are scarcely beyond the combined experimental error of both methods.

Sensitivity to Glycerin Extract of Suprarenal Cortex in Schizophrenia.—Freeman and Hoskins administered a glycerin extract of suprarenal cortex to healthy male schizophrenic patients and to normal subjects in a daily dosage representing approximately 450 grains (30 Gm.) of cortical substance. In a first series of subjects in which the medication was administered for two weeks, two of eight normal controls and eight of nine patients showed a pressor reaction. In a second series in which the medication was administered

for four weeks, one of nine normal controls and seven of ten patients showed a pressor response. Combining the two series, 18 per cent of the normal subjects as compared with 79 per cent of the schizophrenic patients showed a pressor reaction. In the first series of patients the mean rise in systolic pressure for the group was 17 mm. In the first series of normal subjects the mean rise in the systolic pressure for the group was 2.6 mm. In the second series of patients the mean rise in systolic pressure for the group was 13.6 mm. and for the diastolic pressure 12.02 mm. In the second series of normal subjects there was no change in the systolic blood pressure of the group. The mean diastolic blood pressure rose 3.73 mm.

Pituitary Headache.—Skipp treated eleven patients suffering from pituitary headache (ten women and one man) with posterior pituitary extract by mouth and subcutaneously, with a disappearance of the headaches. The oral treatment consisted of the posterior lobe extract in tablet form and the injections consisted of a solution of the posterior lobe extract. Extracts of the anterior lobe apparently were without benefit. The author explains the headache by an interglandular syndrome that forces the hypophysis to hyperactivity, thus causing it to hypertrophy. As it is contained in the "small skull within the large skull" there is an increase of intracapsular pressure, which produces pressure on the blood vessels and their nerves and the pituitary capsule and thus causes pain. The sudden and lasting relief received by these patients is remarkable. It is evidently due to shrinking of the oversized gland and relieving the hypophysis of hypofunction. There is indication that there is a pronounced hypofunction in many cases in which characteristic pain in the head called headache would indicate hypofunction.

Lymph Canals in Repair of Lesions Due to Incisions and Burns.—With the aid of solutions of vital dyes, McMaster and Hudack studied the lymphatic capillaries in the ear of the mouse during the period of immediate reaction to injuries of various sorts and during the period of repair. The behavior

of lymph canals severed by incision differs greatly from that of the small blood vessels. Instead of closing, they sometimes remain open for as long as forty-eight hours. Materials introduced into the wound pass directly into the lymph canals through their gaping ends, a fact that will explain why infection from incisions is predominant along them. All round an injury the lymph canals are rendered abnormally permeable. So too are the blood vessels, a fact well recognized in the past. From twenty-four to forty-eight hours later, at a time when the blood vessels in the edematous tissue surrounding the injured area are still much more permeable than normal, the draining lymph canals allow far less to escape than usual. The possible reasons for this have been discussed. They participate in the removal of fluid from the edematous tissue. As repair after injury takes place, severed lymphatics may reunite when as yet there are no functioning blood vessels. Later an active hyperplasia of the lymphatic channels occurs, an extraordinarily abundant plexus of minute lymph capillaries budding into the area under repair.

Treatment of Impetigo Contagiosa Neonatorum.—Levin used the following routine treatment for impetigo of the new-born in forty-four consecutive cases. It has been successful in clearing up these cases in seventy-two hours or less, the average duration being forty-eight hours after the institution of therapy. All mature lesions were opened once or twice a day and the infant was immersed immediately for from ten to fifteen minutes in a bath of 1:15,000 corrosive mercuric chloride and a thorough soap bath was given with a mild castile soap. A dusting powder composed of equal parts of bismuth subnitrate, light zinc oxide and mild mercurous chloride was applied freely following the bath. New lesions were opened twice a day and the bath was repeated. After the first day only an occasional lesion appeared and only one bath was usually necessary. The bath should be continued for a few days after the last lesion appears. The dusting

powder is applied freely during this period to the affected parts. Elsewhere, talcum powder is applied freely two or three times a day, special attention being paid to all folds and creases of the skin. When external heat is indicated, this is obtained best by a light tent rather than excessive clothing.

Hemorrhage in Duodenal Ulcer.—The plan of treatment that Howard and Barry have used in hemorrhage in duodenal ulcer, with occasional alterations, is as follows: The patient must remain at absolute rest not only during the time of the active hemorrhage but for a period of from two to three weeks after the stool has become negative. Morphine sulphate is administered for the first few days at frequent intervals to produce this rest. Milder sedatives may be used later. In the more recent cases, especially in patients who are nauseated, vomit or show signs of an excessive tympanites, gastric lavage has been used. This should be done morning and evening, preferably with warm tap water. The regurgitated blood in the stomach is removed and the usual beneficial effects of a gastric lavage are obtained. Since the hemorrhage in these patients depends on the activity of the ulcer, a diet is prescribed immediately, which consists of 3 ounces of milk and cream. This mixture is given at intervals of two hours from 8 a. m. to 8 p. m. These feedings are alternated with sodium bicarbonate, from 20 to 60 grains (1.3 to 4 Gm.) from 9 a. m. to 9 p. m. Tap water is given between the feedings in sufficient quantities to relieve the patient's thirst. On the third to the sixth day, gruels may be substituted for the milk feedings, and, as the hemorrhage is brought under control, the diet is increased. Elimination is regulated by prescribing 1 or 2 ounces (30 or 60 cc.) of liquid petrolatum each day. If needed, enemas should be given every other day and a glycerin suppository may be used occasionally.

Reduction and Fixation of Intracapsular Fractures of Femoral Neck.—Fay outlines a method for the reduction and fixation of intracapsular fractures of the neck of the femur in which the knee of the affected side is flexed to a right angle, the thigh to an angle of 60 degrees and then, with the flexed leg used as a lever, internal rotation of the whole limb is carried out with the thigh adducted. This procedure disengages the fragments. It effectively releases the impinged posterior edge of the distal fragment, which is lying against the proximal fragment. Then, while forced internal rotation is maintained, extension and abduction of the limb follows. This sequence of movements places the fractured surfaces in exact apposition. For maintaining this apposition a sufficient length of time to favor bony union, well padded plaster boots are applied on both legs from the toes to the tibial tubercles. Both legs are held apart in forced internal rotation and abduction by a splint, which is incorporated in the plaster and which serves also to extend moderately the fractured limb by using the sound limb for counterpressure. The fractures are reduced as soon as they are roentgenographed. Reductions are done under gas anesthesia. The patient can receive adequate nursing care without discomfort and may sit up in bed at an angle of 60 degrees as soon as the plaster casts are firm. The fractured limb must be held in abduction at all times. The casts are left in place for ten weeks following reduction. Measurement of the distance between the trochanter and the iliac crest is possible in not too fat patients and is taken frequently. Since the two limbs are abducted equally, this is done by comparative palpation. When the casts are removed, the patient is kept in bed for about two weeks. When the heel of the fractured limb can be raised from the bed without aid, union is sufficiently firm to allow sitting up. Massage is given regularly to the knees and ankles after the removal of the casts and, in another two weeks, walking with crutches or assistance is begun. After this, the patient is allowed to go home and dispense with crutches as soon as walking without them is possible. The author obtained demonstrable bony union in nineteen of twenty-two cases.

Treatment of Recurrent Skin Lesions in Breast Carcinoma.—In treating recurrent lesions in the skin and subcutaneous tissues of the wall of the chest following the surgical treatment of primary carcinoma of the breast, Richards uses a method that consists in fitting to the patient's body a radium

applicator, which he calls "the radium jacket." The foundation of this jacket consists of a layer of felt 0.5 cm. thick, which is fitted to the patient's body. To this, rows of radium needles are stitched on and spaced accurately from one another, so arranged as to provide even irradiation of the entire wall of the chest, from the midline in front round posteriorly as far as it is thought desirable to extend the jacket. When sufficient needles have been attached to the felt to cover the desired area, the whole package is enclosed in pure gum rubber and sealed, and in this form the jacket is applied to the patient's chest and the patient wears it for a period of time which is determined by the radium content of the needles and the filtration of their wall. The needles, 60 mm. in length, which have been used for this purpose, contain 3 mg. of radium element and have a wall thickness of 0.8 mm. of platinum of the standard platinum iridium type. Approximately 100 of these needles are used in the full radium jacket and, with the high filtration resulting in a hard gamma ray radiation and the distance from the skin, it is necessary to leave them in position from ninety to 100 hours in order to secure the desired effect. The reaction that follows is a fairly severe first to second degree erythema with vesication and requires care in its treatment. The application of a cream consisting of equal parts by weight of zinc oxide and castor oil is applied immediately following the removal of the jacket and until the reaction has healed entirely. The cream is applied thickly on gauze and the bandage is changed morning and night. The author states that up to the present time there has not been a case in which local secondaries developed following the foregoing procedure. The disadvantages of the method are that in several cases there has been a rather severe constitutional reaction, accompanied by rise of temperature and a moderate degree of shock, which has required the hospitalization of the patient for several weeks and that, if the treatment fails to control the disease, it results in a fairly marked degree of devitalization of tissue and subsequent treatments by any method are rendered difficult or impossible.

Diet of Donor as Possible Cause of Blood Transfusion Reactions.—To determine the cause of reactions following blood transfusion, Price observed the diet of the donor preceding the transfusion. During the last ninety of 300 transfusions he made a decided effort to eliminate food as a possible cause for reaction by asking the donor to omit his last meal prior to the transfusion. For purposes of comparison, in the first 210 cases the attempt to curb the diet of the donor was not pushed and fifty-eight reactions occurred, or 27.5 per cent. In the last ninety cases in which an effort was made to curb the diet, ten reactions occurred, or 11 per cent. In six cases of the latter group, the donor had had something to eat within the five-hour period. Thus, if one is willing to accept the diet of the donor as a factor in producing reactions, the unexplained reactions in the last ninety cases might be reduced to three, or 3.3 per cent. One reaction was believed to be due to repeated collapse of the donor's vein. Of 125 cases in which the donor had had no food within the five-hour period, ten had a reaction. Four of the reactions were attributed to faulty technic, leaving six that occurred in the entire group in which no food was taken within the five-hour period. Of 125 cases in which the donor is known to have taken food within the five hours prior to the transfusion, 35 per cent had a reaction. The only desirable deduction is that the majority of unexplained reactions in blood transfusions may be avoided by controlling the donor's pretransfusion diet. At present, if any foods are to be classed as "vicious," among them would be milk, meat, eggs and gruels. The exact causative reaction factor is not known, but it is believed to be protein in nature. Observation has led to the belief that it is advisable to ask

the donor to omit coffee because of the cream used. At present, only orange juice is the recommendation given the donor for his pretransfusion diet. Such a recommendation is applicable only to the elective transfusion.

Pneumonectomy and Bronchiectasis.—Of the six cases of successful pneumonectomy, the one that Widsberg reports, a case of bronchiectasis of a duration of five and a half years in a girl of 12 years, involved the right lung, whereas the other five involved the left lung. When bronchiectasis, not amenable to postural drainage and bronchoscopic therapy, is confined to one lobe of a lung, lobectomy offers a reasonably good prospect for a complete cure. The method of Graham not only establishes drainage but also destroys diseased lung tissue in multiple stages. In the author's case the method of Graham was employed to begin with because of the multiple cavities and the extensive involvement. Amputation at the hilus was effected at the fourth sitting when it appeared relatively safe. On the other hand, pneumonectomy as a primary procedure would have been hazardous in this case. The wound in the wall of the chest has healed completely except for the opening of a small bronchial fistula high up in the axilla, the size of a pinhead. The fistula has closed, only to open again, on several occasions. Injection of iodized oil shows it to be about 1½ inches in length and to lead directly to the stump of the main bronchus. It is felt that a partial thoracoplasty may be required to effect permanent closure of the fistula as well as to overcome the extreme deviation of the trachea to the right. During the past year the patient has gained in weight and in height. She has carried on well under unfavorable home conditions. Moderate dyspnea develops only following considerable exertion. Cough and expectoration are insignificant and are due entirely to the presence of the bronchial fistula. Since September 1933 she has been attending school for the first time in her life.

Molds as Etiology of Asthma and Hay Fever.—Prince and his associates have encountered cases of severe asthma, both with and without hay fever, that have defied all attempts

at etiologic diagnosis and consequently have received little benefit from therapy. These cases for the most part appear in the fall, about October, and persist with remissions until March or April. The remissions are experienced generally during warm clear weather when the wind is from the Gulf. They began a series of air-borne mold cultures in June 1933. From the roof of a building, sterile plates of Sabouraud's agar were exposed to the air for intervals of two minutes each. These plates were allowed to incubate at room temperature until colonies appeared, which usually required from five to seven days. It was somewhat surprising to find that these short exposures usually resulted in one colony, sometimes more, on each plate. When the time of exposure was increased to five minutes, the colonies were so numerous that mutual contamination could not be avoided. Several cultures of molds were obtained also from the air within doors. In three instances the cultures were obtained from known sources: mold 10, cultured from corn smut, mold 27 from a trichophyton and mold 28, which was an alternaria. Thus, the authors obtained twenty-nine different cultures during the months of June and July. The colonies generally assumed enough gross characteristics within a week to be roughly differentiated, after which they were fished off and inoculated into liquid Sabouraud's mediums in 1,000 cc flasks for quantity yields. After all growth had ceased in the flasks, which required usually from fifteen to twenty days, the pellicles with all spores and mycelia were carefully removed, washed to remove the culture mediums and dried in individual desiccators over calcium chloride. Weighed amounts of the dried material were ground in a mortar and extracted for forty-eight hours in a medium containing one third Coca's fluid and two thirds glycerin, all extractions being carried out in the ratio of 1 Gm of mold to 40 cc of extracting fluid (25 per cent). The extracts were then subjected to Berkefeld filtration and the sterile extracts stored in rubber-stoppered bottles and numbered. A double check for sterility was performed, one plating being made on Sabouraud's agar to determine whether any spores had escaped filtration and a second on ordinary nutrient agar to check for bacteria. Testing sets were prepared from these stock solutions by simple dilution. Coca's solution alone being used as the diluent, so as to avoid a high concentration of glycerin. Two sets of dilutions were prepared, 1:2,000 and 1:500. All the subsequent testing was performed by the intracutaneous method, 0.02 cc being introduced into the superficial layer of the skin in the usual manner. In no case was the 1:2,000 dilution found to be too strong, the less sensitive cases were tried on the 1:500 extract. It was not found necessary to run control tests on the patients, because in each instance several extracts failed to react and these were considered negative. Altogether the authors have tested eighteen patients with their mold extracts. Four normal medical students gave negative reactions. In two asthmatic and one hay fever patient, results were likewise negative, eventually other causative factors were found. Three other asthmatic patients, in whom the cause is known to be a bronchial infection, have reacted strongly to certain of the molds, in two the injections of mold extracts were without benefit, while the third was not treated. Another asthmatic patient sensitive to house dust gave positive reaction to three molds but was treated with dust extract because his symptoms occur chiefly in Austin, Texas, where molds are much less abundant. A difficult hay fever patient is making good progress with mold therapy. The author discusses the six remaining cases that gave positive reactions to molds in which mold therapy has been distinctly encouraging.

Trichomonas Vaginalis Vaginitis—Karnaky presents a method for the diagnosis of *Trichomonas vaginalis* that may be useful to those who have not examined many smears or who are not familiar with this organism. With this method, a few drops of dilute gentian violet stain is mixed well with the smear on the slide. The epithelial cells, pus cells and debris are stained purple, the parasites are not stained at first but may be seen swimming around in a purple surrounding. Later they will take in some of the purple granules and will have a purplish tint. The warm dilute gentian violet preparation is made by adding 6 or 8 drops of gentian violet to 5 cc of warm tap water.

Simplified Treatment of Eclampsia.—To stop convulsions, Rucker's main reliance has been the intravenous administration of magnesium sulphate. He gives 20 cc of a 10 per cent solution. If the convulsions recur, he repeats it once or twice. When the magnesium sulphate failed, he has used sodium amytal intravenously. External stimuli, such as noise, bright lights and jarring the bed, should be avoided. Rest cannot be emphasized too strongly. For this reason the author has abandoned colonic irrigation and gastric lavage. If the patient is in labor he gives morphine and scopolamine or sodium amytal and scopolamine so as to keep her as comfortable as possible in the first stage. For second stage anesthesia he prefers local infiltration of the perineum with 0.5 per cent procaine hydrochloride. To avoid the suppression of urine, he gives plenty of water. If the patient is conscious, she is encouraged to drink water and weak lemonade. Otherwise, a pint of water is poured into the stomach through a nasal tube every eight hours. If more is necessary, hypertonic solution of dextrose may be given intravenously. Edema of the lungs is combated with digitalis. He gives half a cat unit dose of digitalis as early in the treatment as possible. When this is done, edema of the lungs does not develop. When the patient is brought in after a number of convulsions and she has already begun to froth at the mouth, he believes that it is wise to take from 500 to 600 cc of blood from a vein. After the convulsions are controlled, the treatment is tapered off with small doses of sodium amytal, 3 grains (0.2 Gm) two or three times a day, or with sodium bromide and chloral hydrate. For several days the diet should consist of fruit juices. On the whole, the author thinks that it is unwise to allow the patient to leave the hospital undelivered. However, there are exceptional cases that can be carried closer to term under careful supervision. He has treated 123 consecutive cases of eclampsia, with a gross mortality of less than 5 per cent.

Gold Treatment of Pulmonary Tuberculosis. C. Mayer.—p. 131.

Influences Adverse to Tuberculous Patients.—Keddie, in a survey of 262 cases, observed that a large proportion of the cases of pulmonary tuberculosis are reported to the public health authority when the disease is far advanced and that, therefore, in comparatively few instances can one expect ultimate permanent arrest of the lesion. The majority of cases, whether early or advanced in type, fail to secure adequate initial residential treatment. While the medical practitioner is partly responsible for so many patients presenting themselves for public medical treatment at a late stage, the patient is more at fault. Though lack of education in regard to the need for early and adequate treatment is commonly the factor at work, domestic difficulties are not infrequently the important causal influences. On return from residential treatment the patient has in many cases to face housing conditions that are almost certain to be deleterious to his health, and in many instances inadequate food is an adverse influence, being usually present as a result of the inability to secure suitable work for which there is physical capacity. The author is of the opinion that, in order to secure the amelioration of the conditions under which tuberculous patients and their families so commonly live, conditions which undoubtedly cause the patients to relapse or hasten their deaths, and which are practically certain to lower markedly the resistance to infection of the house contacts, there is urgent need for the rehousing of many cases and for the establishment of a care and after care organization.

*Pulmonary Tuberculosis in Asthma Cases. E. M. Fraenkel.—p. 513.

Transmission of Trypanosomiasis, Leishmaniasis and Yaws.—Thomson and Lamborn point out that nonbiting hematophagous muscids feed readily to repletion on blood, serum, serous exudate, ulcers, sores and also secretions from the nose, eyes and mouth. After a meal a certain proportion of these flies pass blood or serum in their numerous dejecta, which may contain large numbers of living trypanosomes, leishmania or the *Treponema pertenue* of yaws. These hematophagous flies have their preferred hosts: *Musca spectanda* Wied favors man. It lays its eggs exclusively in human feces, breeding freely. It derives moisture from human feces and could thus take up *Leishmania donovani* from this source, since the organism is known to occur sometimes in this medium. Large numbers attack persistently and with determination scratches, cuts and sores of the skin of man in search of food and also haunt the eyes, nose and mouth in search of fluid. *Trypanosoma brucei* in the blood of rats and dogs are readily ingested by *Musca spectanda* and during a period varying between five minutes and six hours these flagellates can be passed alive in the numerous droplets of dejecta passed through the intestine of the fly. Rats were experimentally infected by the intraperitoneal injection of these dejecta by a drop placed on a fresh cut on the ear and by the dejecta placed on a drop of blood exuding from the bite of a tabanid. *Trypanosoma brucei* in the dejecta introduced into the eye, nose and mouth did not produce infection. Certain flies after a feed extrude a drop of the ingested blood containing living trypanosomes from the proboscis from five to ten minutes after a full meal. Living leptomonads in cultures of *Leishmania donovani*, infantum (dog strain) and tropica are

freely ingested by *Musca spectanda* and are passed viable in the droplets of excreta for several hours after a feed. There can be no doubt that these flies could ingest the round tissue forms of all the human forms of leishmaniasis and pass them in a viable state either through the intestine or by regurgitation from the proboscis to sores or mucous membranes. It would seem certain that both kala-azar and oriental sore might be actively transmitted through the agency of these flies. The *Treponema pertenue* of yaws passes rapidly in a viable form through the intestine of *Musca spectanda* and so might be deposited easily on cuts and abrasions.

Pulmonary Tuberculosis in Asthma Cases.—Of 369 cases, sent to Fraenkel, diagnosed as bronchial asthma, investigation showed that active tuberculosis was present in sixteen. In two instances a suggestive history was obtained. In one the undiagnosed patient's wife developed tuberculosis of the eyes and in another two children had tuberculous meningitis and pulmonary tuberculosis. It would appear that tuberculosis may become established after asthma alone has been recognized. The asthma may, as a result of an allergic predisposition, be at first monovalent, later becoming polyvalent. The possibility of a secondary hypersensitiveness to tuberculous allergens now arises. Thus, a chemist's assistant who possessed a sensitization to sodium salicylate with typical asthma later developed a rapidly progressive exudative tuberculosis with persistence of the asthmatic picture. There could be no doubt that this patient had previously been completely free from tuberculosis. Another case was that of a medical man who had had asthma practically all his life and became infected with tuberculosis while working in the tuberculosis department of a hospital. This infection led to cavity formation and after treatment was followed by healing. The history of the patient frequently shows an "influenza" infection or a catarrh of the apex. In some of such cases there is found an inactive tuberculosis, which can be demonstrated only by roentgenograms. The most important aspect of these observations is the fact that an active and open tuberculosis can be concealed for a lengthy period under the guise of a bronchial asthma with both eosinophilia and skin reactions against specific proteins.

*Aneurysm of Popliteal Artery. J. Dunbar.—p. 102.

Aneurysm of Popliteal Artery.—Dunbar reports a case that presented an expansile swelling in the middle of the lower half of the left popliteal space. Pressure over the superficial femoral artery caused the pulsation to disappear. There was slight delay of the pulse in the left posterior tibial artery. Slight venous congestion of the leg was present with enlargement of the superficial veins, especially one from the upper end of the short saphenous running upward and inward to the long saphenous. There was no difficulty about the diagnosis. Roentgen examination failed to show any definite shadow corresponding to the aneurysm. To investigate the shape of the aneurysm, neo-*iopax* was injected into it through a fine needle. Roentgenograms showed the aneurysm to be of the fusiform variety, with a marked constriction of the artery about 1 inch below the aneurysm. The artery was slightly dilated between the aneurysm and the constriction. To open up an efficient collateral circulation, pressure by means of a tourniquet (Skey's) was applied to the superficial femoral in Hunter's canal. The patient was able to carry out the treatment unaided. At first he could keep the tourniquet in position for only five minutes at a time. This was repeated three times a day and the length of time was gradually increased until in three weeks he could stand it for thirty minutes without discomfort. A posterior median vertical incision was made over the swelling, the large vein noticed on examination being avoided. The sac was easily found and the vein and nerve, lying on its outer posterior aspect, were carefully dissected from the sac. After the sac had been completely exposed it was found impossible to expose the constriction of the artery without causing considerable damage to the nerves. Therefore the aneurysm was removed between ligatures. The patient was discharged from the hospital fourteen days later, having made an uneventful recovery.

Disturbances of Body Temperature.—Lakin observed that metabolism is responsible for heat production, that a center in the hypothalamus is concerned with the regulation of body temperature and that the center is so constituted as to be sensitive to the temperature of the blood passing through it. If this temperature is raised, the various means for increasing the loss of heat and decreasing its production are brought into play. If the temperature is lowered, those for decreasing the loss of heat and for increasing the production of heat become operative. The thyroid and suprarenal acting through the sympathetic nervous system influence metabolism and together form a "humoral apparatus" (Cramer) concerned in the regulation of the heat of the body. The heat center may be regarded as a group of nerve cells representing the central connections of the sympathetic. When it is considered that during muscular exercise the production of heat may be increased from 200 to 300 per cent without the temperature rising, whereas in fevers production of the heat may be increased only from 20 to 30 per cent and yet pyrexia results, it is obvious that in cases of fever some lack of adjustment must occur. In infective conditions pyrexia must be regarded as the resultant of two forces: the toxic action of the invading organism on the one hand and the resistance of the infected person on the other. Such a conception is borne out when the temperature chart is studied in conjunction with the curve of the opsonic index. The elevations on the temperature chart correspond to depressions of the opsonic curve and vice versa; that is, the temperature chart bears an inverse relationship to the opsonic activity. Since aseptic suppuration is accompanied by fever, some investigators ascribe the fever and chills that occur in cases of suppuration to the absorption of autolytic products rather than to the direct action of poisons produced by the invading organisms. The rise of temperature that occurs when a patient gets up too soon after a pyrexial illness is to be ascribed to the increased cardiac action (consequent on the increased exertion) washing out inflammatory products from the affected area into the general circulation. The occurrence of pulmonary infections after anesthesia is perhaps favored by the thyroid and suprarenal exhaustion that follows the exhibition of general anesthetics.

*Possibility of Local Vitamin Insufficiency: Theoretical Considerations and Therapeutic Application. S. Balachowski.—p. 1404.

Local Vitamin Insufficiency.—Balachowski believes that the only proof of a local vitamin insufficiency lies in the therapeutic results of supplying the vitamin locally. In attempting to answer this question he used a colloidal preparation of carotene for local application. The direct application of this preparation at the site of different local conditions resulted in numerous successful therapeutic effects and often in a remarkable analgesia. Without desiring to formulate the indications for local carotene therapy, he believes that its study is interesting in superficial ocular lesions (conjunctivitis, keratitis, ultraviolet lesions, certain forms of trachoma, and so on), gingivitis, cracks of the breasts, anal fissures, burns and a few other similar local abnormalities.

*Early Diagnosis and Treatment of Intestinal Invagination of Nursling. E. Pouliquen.—p. 1421.

Intestinal Invagination of Nursling.—Pouliquen discusses the diagnosis and treatment of intussusception in infants. When the classic signs of occlusion, restlessness and bloody stools exist, the diagnosis offers no difficulties. When, however, the bloody stools are delayed or absent, this diagnosis is much more difficult to make at the first visit. Vomiting, colic and palpation of a filled intestinal loop are also frequently helpful. Rectal examination often clarifies the diagnosis because of the palpable mass or because blood tinged stool or mucus is often obtained. Roentgenologic examination is of great importance. In fact, the author feels that when invagination is suspected the physician should think immediately of the x-rays and the possibility of obtaining consultation by telephone. Two types of treatment come under consideration. These are enemas and operation. The author feels that one or two barium enemas suffice and, if the massive passage of barium into the small intestine occurs accompanied by disappearance of the palpable filled intestinal loop, proof of its effectiveness exists. Operation when used should be performed immediately and rapidly and should involve the tactile reduction of the invagination. Resection is rarely successful.

Action of Hormones and Mercurial Diuretics on Evolution of Histamine Blister.—Steffanutti and Jantria state that the histamine blister is made up of two fundamental factors, the first of which is exclusively vascular by nature and is due to capillary dilatation and transudation of plasma fluid from the capillary walls. The second phase is a condition of local edema produced by stagnation of the transudate in the meshwork of the cutaneous tissues. The authors studied the influence of such important hormones as epinephrine, solution of pituitary, thyroxine, insulin and extract of the anterior hypophysis and of mercurial diuretics on the second stage of the blister. They observed a diminution of the blister when extracts of the hypophysis and insulin were administered and a continuous evolution when a thyroid hormone substance was given simultaneously with mercurial diuretics. They give the following explanation: The first two substances increase the power of absorption of the cutaneous tissues in the presence of transudates, while the latter diminish this absorptive power. This explanation is in accord with the current ideas concerning tissue action of the hormones and with the effect of mercurial diuretics on water metabolism. They believe that the histamine blister is particularly adapted to the study of the inhibitory power of such substances on the tissues.

Treatment of Gastroduodenal Ulcer with Injections of Sodium Benzoate.—Liberti treated fourteen patients who had gastric and duodenal ulcers with daily intravenous injections of 2 cc. of a 25 per cent solution of sodium benzoate. The patients were not placed on a strict diet but were advised against drinking alcoholic beverages, smoking and eating acid foods and condiments. The injections were given for from twenty to forty consecutive days, depending on the resistance of the disease to treatment. Two patients showed complete cure after thirty injections, while eleven had a temporary clinical and roentgenologic improvement with eventual recurrences of the disease symptoms within from two to six months. One patient evinced no improvement after the maximum number of injections. The author does not attribute any specific curative power to the sodium benzoate but considers it an effective and useful adjuvant to the medical treatment of gastric and duodenal ulcer.

*Variations of Arterial Blood Pressure in Relation to Changes of Intrapulmonary Atmospheric Pressure. J. A. Adrio Mateo.—p. 316.

Blood Pressure and the Intrapulmonary Atmospheric Pressure.—Adrio Mateo concludes that the arterial blood pressure in normal persons diminishes when the ambient barometric pressure increases and rises when the ambient barometric pressure diminishes. Persons suffering from vasomotor disturbances of nervous instability and those with vasomotor neurosis react to the barometric changes by showing variations of the arterial blood pressure similar to those shown by patients suffering from arteriosclerosis or circulatory diseases. The reaction in these patients, however, is not of a clear type. The arterial pressure in patients with arteriosclerosis, either of the decompensated or of the slightly compensated type, as well as that of those suffering from a circulatory miopragia, descends to normal figures when the ambient barometric pressure increases, just as in normal persons and in those having compensated arteriosclerosis, but descends abnormally when the barometric pressure diminishes. The lowering of the arterial blood pressure in the last mentioned case may be considered a cardiac failure rather than a reaction. It is, in fact, a cardiac claudication. The results of the author's observations explain the frequent appearance of decompensatory and vasomotor disturbances and the general feeling of illness in arteriosclerotic patients under sudden changes of atmospheric pressure. They also show the importance of meteorological pathology as a science in which the clinician and the meteorologist, working together, will enlighten the mechanism of action of the atmospheric pressure on the arterial blood pressure as well as many other facts not as yet clearly understood.

Evaluation of Power of Resistance of Organism in Surgical Practice.—According to Schürer-Waldheim, the power of resistance is dependent to a great extent on the functioning of the reticulo-endothelial system, particularly in combating infectious processes. Numerous errors have crept into the methods of estimation of the functional capacity of the reticulo-endothelial system. Erroneous conclusions were frequently arrived at from the so-called functional storage tests. The author has investigated with the aid of an exact photometric method the applicability in surgical diseases of the test of functional storage capacity of the reticulo-endothelium, in particular the colorimetric method of determining the amounts of congo red in the blood serum, according to the method of Adler and Reimann. His experiments demonstrated that the

amount of congo red in the serum does not constitute an index of the functional capacity of the reticulo-endothelial system. He leans to the views of Letterer and of Bennhold that the excretion of the injected congo red takes place with the aid of serum albumins and that little of it is taken up by the reticulo-endothelial cells. A fairly valuable partial functional test is offered by the method of a cytologic study of the contents of a cantharides blister as proposed by Kaufmann. Determination of the natural immune bodies in the blood according to the method of Wright (opsonic index) is another valuable method of estimating the power of resistance. The author describes several minor modifications of the Wright method, which are time saving, and cites clinical examples of the great practical value of determining the bactericidal power of an organism in combating septic processes.

Anastomosis of Intrahepatic Bile Duct with Stomach or Intestine.—Gohrbandt describes two surgical methods for the relief of icterus due to complete occlusion of the entire hepatic duct up to the point of exit from the liver. One method consists of puncturing the liver with a trocar 24 cm. long and 1 cm. wide and introducing a rubber tube. The second method consists of a direct anastomosis of an intrahepatic bile duct with the stomach or duodenum, a rubber tube being utilized as a prosthesis. The finding of a distended bile duct on the surface of the liver is not difficult. The duct is cut across and a rubber tube or an artery forceps is introduced while the bile is still flowing. The lumen of the duct may be stretched, if necessary, with the aid of an artery forceps to twice its size. The rubber tube is secured to the wall of the duct by a fine stitch to prevent slipping out. It is then anastomosed to the stomach or duodenum by the method of an oblique fistula formation. The stomach is preferable because of its motility, but the author warns that it is only the acid-containing stomach that will tolerate bile well. The serosa of the stomach or the intestine is sutured to the serosa of the liver about the point of exit of the rubber tube and its entry into the stomach or duodenum. The author reports one case in which trocar puncture and drainage was practiced and three cases in which he performed a direct anastomosis of an intrahepatic duct with the stomach. In all three cases obstruction was due to a malignant growth. This method makes it possible at least to relieve the patient from the effects of the obstructive icterus.

Diagnosis and Prognosis of Bone Tumors.—Glauner presents a study of seventy-seven cases of bone tumor selected from the material of biopsies and operatively resected specimens received at the pathologic institute of the München-Schwabing Hospital. While this is principally a histologic study, the author utilizes the histories, the roentgenologic studies and a follow up to complete the picture of each case. The study is concerned with the following questions: 1. Is histologic examination a competent criterion of benignity of a bone tumor that clinically and roentgenologically suggests a sarcoma? 2. Can the recently differentiated forms of sarcoma be recognized as definite entities with regard to their diagnosis, prognosis and treatment? The study is concerned also with methods of treatment and results as well as with the influence of trauma and of internal secretions. The material consists of four groups. In the first group there were ten cases of benign bone tumors; the second group had twenty-seven cases of undifferentiated sarcomas—spindle cell, round cell and Ewing sarcomas; in the third group there were twenty-two cases of differentiated chondro-osteomyxosarcomas and their combinations, and in the fourth group eighteen cases of benign processes resembling sarcoma, such as osteitis fibrosa localisata and Paget's osteitis deformans. The author concludes that a histologic study is capable of establishing the benign nature of a tumor. The clinical and roentgenologic information is of secondary importance in arriving at this diagnosis; therefore the importance of a biopsy. The roentgenologic appearance of fibrous osteitis, even if supported by a characteristic clinical history, is not a reliable criterion. The same can be simulated by a breaking down chondroma, osteoma and, even more frequently, by a chondrosarcoma and its metastases. The cavity should be curetted and the obtained material studied histologically. The excochleation suffices as treatment for osteitis fibrosa, as proved by the results in their cases. If the process becomes more extensive or displays a tendency to metastasize, a resection

becomes the method of choice. The true sarcomas yield a high mortality regardless of the method of treatment. The greater number of the few who survived a number of years were intensively irradiated with roentgen rays both before and after the operation. Irradiation was found to produce a fibrotic change in the histologic picture. The diagnosis of Ewing sarcoma can be made with assurance only on histologic examination. The prevailing notion that it grows along the shaft of a long bone is not correct. It is located close to a joint, as are the other sarcomas. Because of the difference in the treatment, an accurate diagnosis is particularly important in this group of tumors. Trauma seldom plays a part in the origin of sarcoma. In localized fibrous osteitis, on the other hand, a corresponding local trauma was shown to have existed in every case. The histologic picture of localized fibrous osteitis in the author's experience coincided with that generally described. Differentiation before puberty from a sarcoma was at times impossible. Typical giant cells, when present, simplify the differentiation. The author did not find a single instance of transformation of a localized fibrous osteitis into a general one, nor were disturbances of internal secretions observed in the localized form. Localized fibrous osteitis is a distinct disease of the young resulting from a trauma. The histologic differentiation of Paget's osteitis from fibrous osteitis of older patients may present considerable difficulties. The macroscopic appearance of the bone is of the greatest importance. The conditions are separate entities, Paget's disease occurring in old persons, mostly in women.

Oxygen Insufficiency as Cause of Angina Pectoris.—

Von Bergmann says that the pathogenesis of angina pectoris has been explained on the basis of two theories, the coronary and the aortic. He rejects the aortic theory. In discussing the coronary theory he mentions experiments proving that, while the constriction of other vessels is controlled by the sympathetic, the coronary vessels are controlled by the vagus and that the blood supply of the cardiac muscle is adapted to the functional requirements of the heart. If the heart has to meet greater functional requirements, the coronary vessels become wider and the blood perfusion and oxygen supply increase. The author cites experiments (pressure on the vagus and clinical manifestations (the gastroduodenal syndrome) proving that a disturbance in the blood and thus in the oxygen supply of the heart muscle can be produced by neurogenic action. Still more important is the fact that an increase in the blood pressure in the carotid sinus produces by action an increase in the tonus of the cardiac vagus. This increase becomes severe, as for instance in Pal's vascular contraction of the coronary vessels occurs, the oxygen supply of the heart becomes deficient and angina pectoris may result. The author points out that he definitely accepted severe coronary ischemia in the cardiac muscle as the cause of angina pectoris. In recent years, as he cites electrocardiographic studies and in total constriction of the coronary vessels is the main factor in the development of oxygen deficiency in the heart muscle.

Syndrome of

histories of two patients with narcolepsy coexisted with development make it apparent that patient sustained while

ment of the narcolepsy as well as of the acromegaly. Observations on the cerebrospinal fluid and on the sella seem to indicate a hypophyseal tumor. Indications of the existence of a cerebral tumor existed also in the second patient. This one had sustained a concussion of the brain thirty years before the attacks of narcolepsy became manifest, but several years previous to that accident he had lost the formerly normally developed hair of the head and of the pubic region. Both patients had the typical symptoms of narcolepsy: attacks of sleep, attacks of loss of tonus and a disturbance of the nocturnal sleep. As the main reason why these cases were reported, the author mentions disturbances in the heat regulation. There existed considerable discrepancies between the axillary and the rectal temperatures. At times the axillary temperature was much higher than the rectal and at other times the rectal was higher than the axillary. The author points out that, considering the close proximity of the center of sleep and of the center of heat regulation, disturbances in the temperature of patients with narcolepsy are not surprising. The literature reports a case of narcolepsy with hypothermia and also calls attention to the fact that the impairment of the sympathetic functions have not been given sufficient attention in patients with narcolepsy. The author is unable to decide whether the disturbance in the heat regulation of his patients is due to morphologic changes in the brain itself or whether hormone actions of the impaired hypophysis are responsible.

H. Klein show a general inheritance. Hemolytic jaundice runs through four cases of hemolytic jaundice of the classic type is important but also for observations, the course of development is yet unable to be determined to hemodynamically wide striding eyes, thus, progression, misplacement, Dupuytren's contracture, accessory nipples, skin atrophy.

to
tires
tients
he main
increased
impression
nature is only

regional. He assumes that the disturbance in the thermoregulation of persons with protracted hyperthermias is connected with nervous-vascular disturbances. These disorders develop readily in patients with sympathetic instability. In the disturbances of the thermoregulation that exist in exophthalmic goiter and after acute diseases the same mechanism seems to obtain. Krehl spoke of an atactic condition of the involved organs. It is probable that this ataxia, which involves primarily the nervous-vascular mechanism, is sufficient to disturb the normal blood-heat distribution of the organisms. This development of disturbances of the temperature makes it understandable why there is no increase in the metabolic rate, in the oxidation processes and in the heat production. The disturbance in the temperature is rather the result of abnormal regional distribution and of heat elimination. It is not known how this comes about, but it is probable that insufficiencies of the natural barriers of the organism, such as the blood-cerebrospinal fluid barrier, the vascular endothelial barrier and the intestinal barrier, permit toxic substances to enter the regulatory apparatus of the central nervous system, which ordinarily do not enter it. It is possible also that the nervous regulatory ataxia is due to fatigue of the central apparatus. The part played by the endocrine system in the pathogenesis of protracted hyperthermias becomes easy to understand on consideration of the close connections between the endocrine glands and the sympathetic nervous system. Thus it is not the infectious, inflammatory processes or other localized anatomic changes that cause the protracted hyperthermia but rather a change in the reaction of the patient's organism, particularly in his sympathetic nervous system. In treating protracted subfebrile temperatures, the suggestion of different diagnoses and of numerous treatments should be avoided. A change in the mode of life and methods of physical therapy, such as water cures and galvanization of the cervical portion of the spinal column, may be tried. A sojourn in a sanatorium or in a rural district may be helpful.

Predisposition to Thrombosis in Polycythemia Vera.—Jürgens and Bach observed seven cases of polycythemia vera, of which three presented thrombosis. All the patients with thrombosis showed increase in thrombocytes, shortening of the time of thrombosis (capillar-thrombometer) and of the agglutination of the platelets and also increase in fibrinogen and globulin. In the four patients with polycythemia vera who were free from thrombosis, these changes were absent. This indicates that not all patients with polycythemia have a predisposition to thrombosis, but only those whose blood shows certain changes. The authors think that in addition to the increased fibrinogen and globulin content the thrombocytosis plays an important part in the formation of thrombi. They emphasize that the measurement of the thrombosis time, the counting of the thrombocytes and the examination of the plasma proteins are methods that will reveal a predisposition for thrombosis without having to take into account the vascular factor, the detection of which is difficult. This is important for the treatment. Roentgenotherapy of the bones of patients with polycythemia reduces the number of thrombocytes and normalizes the thrombosis time and the plasma protein.

Testing Pulmonary Function by Means of Histamine.—To determine the functional capacity of the lung, Heymer and Grosse-Brockhoff employed a test that was introduced by Klein and Nonnenbruch, who had found that the subcutaneous injection of from 1 to 2 mg. of histamine inhibits the oxygenation of the lung. The authors report their observations on 100 persons. In patients with disturbances of the pulmonary circulation, the subcutaneous injection of 1 mg. of histamine is followed by increase in the oxygen saturation of the arterial blood, reduction of the vital capacity and of the respiratory pause. The degree of all these changes is clearly a dependence on the severity of the clinical picture of the disorder. Persons with pneumothorax show a similar behavior. The method is especially suitable for the diagnosis of latent disturbances of the lungs and of the pulmonary circulation and is of great value in determining the effect of collapse therapy.

Application of Alpha-Dinitrophenol.—The authors are convinced de Châtel and Motika that alpha-dinitrophenol is not a harmless drug, for even if given in small doses it produced symptoms that indicate an

impairment of the kidneys and of the myocardium. The cardiac disturbances were demonstrated in electrocardiographic tests on the patients and they were corroborated in experiments on cats. Moreover, dinitrophenol does not always accomplish its aim, for in one of the patients the highest therapeutic doses changed neither the metabolism nor the body weight, and in the other one the weight did not decrease much until the sense of taste had become impaired and the patient had lost her appetite.

*Serodiagnosis of Syphilis by Means of Hemagglutination Reaction of Bachmann. G. Petzelt.—p. 1282.

Modified Takata Reaction.—Jezler's report is based on the necropsy material of the medical clinic in Basel. A tabular report of the clinical tests reveals that glomerular nephritis is the only one of the nonhepatic disorders in which the Takata reaction is positive, but in these cases the diagnosis can be based on other clinical symptoms. Another tabulated report indicates the necropsy diagnoses of 264 cases, 104 of which had given a positive Takata reaction. The hepatic changes found in these 104 cases are presented in another table. This table shows that cirrhosis was present in 70 per cent of the cases, engorged liver in 10 per cent, atrophy of the liver in three cases and fatty liver in six cases. The author points out that von Bergmann has emphasized the rôle of fatty liver in the development of hepatic cirrhosis. In the remaining cases there existed conditions such as cholangitic abscess, syphilis, carcinoma and tuberculosis, and in two cases the pathologic anatomic changes were insufficient to explain a positive Takata reaction. These results indicate that the Takata reaction cannot be considered a definite indication of cirrhosis of the liver, for a number of other hepatic changes may cause a positive outcome of the test. Moreover, although with the exception of the cases of glomerular nephritis a positive Takata flocculation usually proves the existence of a hepatic impairment, a severe hepatic disorder does not necessarily produce a positive Takata reaction. Even in some cirrhotoses, particularly in the hemochromatotic forms, a disturbance of the colloidal equilibrium may be absent. In reply to Pongor, who stated that in patients with pulmonary tuberculosis a positive Takata reaction was indicative of an active process, the author replies that in seventy-one cases of open tuberculosis the reaction was positive in only ten. Eight of these could be subjected to necropsy, and in all of them hepatic changes were present.

Diagnosis of Syphilis by Hemagglutination Reaction.—Petzelt states that Bachmann described the serologic diagnosis of syphilis in the active serum by means of the hemagglutination of sheep corpuscles by specific rabbit immune serum. Bachmann based his test on the following observation: If an otherwise normally titrated hemolytic system is intensified, as in the Wassermann test, by the addition of several drops of concentrated amboceptor, the negative serums usually show in the main experiment a more or less pronounced inhibition of the hemolysis, while all positive serums reveal agglutination of the erythrocytes. However, if for the main test active serum is used without the addition of guinea-pig complement, the positive serum, to be sure, produces again strong agglutination, but the negative serum produces complete hemolysis. According to Bachmann, the hemagglutination reaction can replace the other inactive methods of the Wassermann reaction. The author verified the Bachmann test on 506 serums, following Bachmann's technic in every detail. A comparison of the results of the Bachmann test with the Wassermann and Kahn tests revealed to the author complete conformity of the three tests in 76.87 per cent of the cases. A consideration of the sure cases of syphilis (427 of 506) showed that the hemagglutination reaction was specific in 84.4 per cent of the cases. In the other seventy-nine cases an estimation of the specificity was impossible because clinical data were not given.

becomes the method of choice. The true sarcomas yield a high mortality regardless of the method of treatment. The greater number of the few who survived a number of years were intensively irradiated with roentgen rays both before and after the operation. Irradiation was found to produce a fibrotic change in the histologic picture. The diagnosis of Ewing sarcoma can be made with assurance only on histologic examination. The prevailing notion that it grows along the shaft of a long bone is not correct. It is located close to a joint, as are the other sarcomas. Because of the difference in the treatment, an accurate diagnosis is particularly important in this group of tumors. Trauma seldom plays a part in the origin of sarcoma. In localized fibrous osteitis, on the other hand, a corresponding local trauma was shown to have existed in every case. The histologic picture of localized fibrous osteitis in the author's experience coincided with that generally described. Differentiation before puberty from a sarcoma was at times impossible. Typical giant cells, when present, simplify the differentiation. The author did not find a single instance of transformation of a localized fibrous osteitis into a general one, nor were disturbances of internal secretions observed in the localized form. Localized fibrous osteitis is a distinct disease of the young resulting from a trauma. The histologic differentiation of Paget's osteitis from fibrous osteitis of older patients may present considerable difficulties. The macroscopic appearance of the bone is of the greatest importance. The conditions are separate entities, Paget's disease occurring in old persons, mostly in women.

Oxygen Insufficiency as Cause of Angina Pectoris.—

Von Bergmann says that the pathogenesis of angina pectoris has been explained on the basis of two theories, the coronary and the aortic. He rejects the aortic theory. In discussing the coronary theory he mentions experiments proving that, while the constriction of other vessels is controlled by the sympathetic, the coronary vessels are controlled by the vagus and that the blood supply of the cardiac muscle is adapted to the functional requirements of the heart. If the heart has to meet greater functional requirements, the coronary vessels become wider and the blood perfusion and oxygen supply increase. The author cites experiments (pressure on the vagus) and clinical manifestations (the gastroduodenal syndrome) proving that a disturbance in the blood and thus in the oxygen supply of the heart muscle can be produced by neuroreflex action. Still more important is the fact that an increase of the blood pressure in the carotid sinus produces by reflex action an increase in the tonus of the cardiac vagus. If this increase becomes severe, as for instance in Pal's vascular crises, a contraction of the coronary vessels occurs, the oxygen supply of the heart becomes deficient and angina pectoris may result. The author points out that he definitely accepted several years ago the theory that ischemia in the cardiac muscle, that is, oxygen deficiency in parts of the heart, is the cause of angina pectoris, and he shows that studies in recent years have furnished the proof of this theory. He cites electrocardiographic studies and he emphasizes that not the coronary spasm with total constriction of a coronary branch is the most important factor in the development of angina pectoris but rather the oxygen deficiency in parts of the cardiac muscle.

Syndrome of Narcolepsy.—Reinwein relates the clinical histories of two patients. In the first patient a symptomatic narcolepsy coexisted with acromegaly. The anamnesis and the development make it appear probable that a trauma, which the patient sustained while boxing, was the cause for the develop-

ment of the narcolepsy as well as of the acromegaly. Observations on the cerebrospinal fluid and on the sella seem to indicate a hypophyseal tumor. Indications of the existence of a cerebral tumor existed also in the second patient. This one had sustained a concussion of the brain thirty years before the attacks of narcolepsy became manifest, but several years previous to that accident he had lost the formerly normally developed hair of the head and of the pubic region. Both patients had the typical symptoms of narcolepsy: attacks of sleep, attacks of loss of tonus and a disturbance of the nocturnal sleep. As the main reason why these cases were reported, the author mentions disturbances in the heat regulation. There existed considerable discrepancies between the axillary and the rectal temperatures. At times the axillary temperature was much higher than the rectal and at other times the rectal was higher than the axillary. The author points out that, considering the close proximity of the center of sleep and of the center of heat regulation, disturbances in the temperature of patients with narcolepsy are not surprising. The literature reports a case of narcolepsy with hypothermia and also calls attention to the fact that the impairment of the sympathetic functions have not been given sufficient attention in patients with narcolepsy. The author is unable to decide whether the disturbance in the heat regulation of his patients is due to morphologic changes in the brain itself or whether hormone actions of the impaired hypophysis are responsible.

Symptomatology and Heredity of Hemolytic Jaundice.

—Hansen and Klein show a genealogical table of a family with fifty-four members. Hemolytic jaundice runs through four generations. In addition to twenty-one typical cases of hemolytic jaundice there are seven that show only parts of the classic syndrome. The detection of these atypical forms is important not only for the diagnosis of hemolytic jaundice but also for the heredity. In corroboration of Gänsslen's observations, the authors noted in this family also a great number of developmental disturbances and anomalies, but they are as yet unable to state whether the anomalies are in any way related to hemolytic jaundice. They observed tower-head, abnormally wide root of the nose, deformities of the palate, protruding eyes, divergent position of the eyes, mongolic fold, epicanthus, prognathism, persistence of deciduous teeth in adults, misplacement of permanent teeth and other tooth deformities, Dupuytren's contracture of the fifth finger, ongrown ears, accessory nipples, extensive crural ulcers, hemangiomatosis of the skin and acne vulgaris. The abnormalities of the eyes were persistent pupillary membrane, ectropion of the pigmented layer on the sphincter of the iris, cloudiness of the lens, bilateral cataracts of the anterior pole, tortuous retinal vessels, myopia, astigmatism and red-green color blindness. The persistent pupillary membrane is surprisingly frequent. It is present in nearly all the patients with hemolytic jaundice. The authors are unable to state whether it is a true syntropy of hemolytic jaundice or a peculiarity of this family. The heredity of hemolytic jaundice is dominant.

Protracted Subfebrile Temperatures.—Gelman tries to answer the question whether protracted subfebrile temperatures can be considered as a true fever process. Tests on patients revealed that in protracted subfebrile temperatures the main characteristic of a fever process is lacking; namely, increased heat production. Moreover, the author gained the impression that in some of the patients the increase in temperature is only

regional. He assumes that the disturbance in the thermoregulation of persons with protracted hyperthermias is connected with nervous-vascular disturbances. These disorders develop readily in patients with sympathetic instability. In the disturbances of the thermoregulation that exist in exophthalmic goiter and after acute diseases the same mechanism seems to obtain. Krehl spoke of an atactic condition of the involved organs. It is probable that this ataxia, which involves primarily the nervous-vascular mechanism, is sufficient to disturb the normal blood-heat distribution of the organisms. This development of disturbances of the temperature makes it understandable why there is no increase in the metabolic rate, in the oxidation processes and in the heat production. The disturbance in the temperature is rather the result of abnormal regional distribution and of heat elimination. It is not known how this comes about, but it is probable that insufficiencies of the natural barriers of the organism, such as the blood-cerebrospinal fluid barrier, the vascular endothelial barrier and the intestinal barrier, permit toxic substances to enter the regulatory apparatus of the central nervous system, which ordinarily do not enter it. It is possible also that the nervous regulatory ataxia is due to fatigue of the central apparatus. The part played by the endocrine system in the pathogenesis of protracted hyperthermias becomes easy to understand on consideration of the close connections between the endocrine glands and the sympathetic nervous system. Thus it is not the infectious, inflammatory processes or other localized anatomic changes that cause the protracted hyperthermia but rather a change in the reaction of the patient's organism, particularly in his sympathetic nervous system. In treating protracted subfebrile temperatures, the suggestion of different diagnoses and of numerous treatments should be avoided. A change in the mode of life and methods of physical therapy, such as water cures and galvanization of the cervical portion of the spinal column, may be tried. A sojourn in a sanatorium or in a rural district may be helpful.

Predisposition to Thrombosis in Polycythemia Vera.

—Jürgens and Bach observed seven cases of polycythemia vera, of which three presented thrombosis. All the patients with thrombosis showed increase in thrombocytes, shortening of the time of thrombosis (capillarythrombometer) and of the agglutination of the platelets and also increase in fibrinogen and globulin. In the four patients with polycythemia vera who were free from thrombosis, these changes were absent. This indicates that not all patients with polycythemia have a predisposition to thrombosis, but only those whose blood shows certain changes. The authors think that in addition to the increased fibrinogen and globulin content the thrombocytosis plays an important part in the formation of thrombi. They emphasize that the measurement of the thrombosis time, the counting of the thrombocytes and the examination of the plasma proteins are methods that will reveal a predisposition for thrombosis without having to take into account the vascular factor, the detection of which is difficult. This is important for the treatment. Roentgenotherapy of the bones of patients with polycythemia reduces the number of thrombocytes and normalizes the thrombosis time and the plasma protein.

Testing Pulmonary Function by Means of Histamine.

—To determine the functional capacity of the lung, Heymer and Grosse-Brockhoff employed a test that was introduced by Klein and Nonnenbruch, who had found that the subcutaneous injection of from 1 to 2 mg. of histamine inhibits the oxygen intake of the lung. The authors report their observations on twenty-one persons. In patients with disturbances of the pulmonary circulation, the subcutaneous injection of 1 mg. of histamine is followed by increase in the oxygen saturation deficit of the arterial blood, reduction of the vital capacity and shortening of the respiratory pause. The degree of all these changes shows clearly a dependence on the severity of the clinical manifestations of the disorder. Persons with pneumothorax show the same behavior. The method is especially suitable for the detection of latent disturbances of the lungs and of the pulmonary circulation and is of great value in determining the advisability of collapse therapy.

Dangers of Application of Alpha-Dinitrophenol.

—Observations in two cases convinced de Châtel and Motika that alpha-dinitrophenol is not a harmless drug, for even if given in therapeutic doses it produced symptoms that indicate an

impairment of the kidneys and of the myocardium. The cardiac disturbances were demonstrated in electrocardiographic tests on the patients and they were corroborated in experiments on cats. Moreover, dinitrophenol does not always accomplish its aim, for in one of the patients the highest therapeutic doses changed neither the metabolism nor the body weight, and in the other one the weight did not decrease much until the sense of taste had become impaired and the patient had lost her appetite.

Modified Takata Reaction.—Jezler's report is based on the necropsy material of the medical clinic in Basel. A tabular report of the clinical tests reveals that glomerular nephritis is the only one of the nonhepatic disorders in which the Takata reaction is positive, but in these cases the diagnosis can be based on other clinical symptoms. Another tabulated report indicates the necropsy diagnoses of 264 cases, 104 of which had given a positive Takata reaction. The hepatic changes found in these 104 cases are presented in another table. This table shows that cirrhosis was present in 70 per cent of the cases, engorged liver in 10 per cent, atrophy of the liver in three cases and fatty liver in six cases. The author points out that von Bergmann has emphasized the rôle of fatty liver in the development of hepatic cirrhosis. In the remaining cases there existed conditions such as cholangitic abscess, syphilis, carcinoma and tuberculosis, and in two cases the pathologic anatomic changes were insufficient to explain a positive Takata reaction. These results indicate that the Takata reaction cannot be considered a definite indication of cirrhosis of the liver, for a number of other hepatic changes may cause a positive outcome of the test. Moreover, although with the exception of the cases of glomerular nephritis a positive Takata flocculation usually proves the existence of a hepatic impairment, a severe hepatic disorder does not necessarily produce a positive Takata reaction. Even in some cirrhotoses, particularly in the hemochromatotic forms, a disturbance of the colloidal equilibrium may be absent. In reply to Pongor, who stated that in patients with pulmonary tuberculosis a positive Takata reaction was indicative of an active process, the author replies that in seventy-one cases of open tuberculosis the reaction was positive in only ten. Eight of these could be subjected to necropsy, and in all of them hepatic changes were present.

Diagnosis of Syphilis by Hemagglutination Reaction.

—Petzelt states that Bachmann described the serologic diagnosis of syphilis in the active serum by means of the hemagglutination of sheep corpuscles by specific rabbit immune serum. Bachmann based his test on the following observation: If an otherwise normally titrated hemolytic system is intensified, as in the Wassermann test, by the addition of several drops of concentrated amboceptor, the negative serums usually show in the main experiment a more or less pronounced inhibition of the hemolysis, while all positive serums reveal agglutination of the erythrocytes. However, if for the main test active serum is used without the addition of guinea-pig complement, the positive serum, to be sure, produces again strong agglutination, but the negative serum produces complete hemolysis. According to Bachmann, the hemagglutination reaction can replace the other inactive methods of the Wassermann reaction. The author verified the Bachmann test on 506 serums, following Bachmann's technic in every detail. A comparison of the results of the Bachmann test with the Wassermann and Kahn tests revealed to the author complete conformity of the three tests in 76.87 per cent of the cases. A consideration of the sure cases of syphilis (427 of 506) showed that the hemagglutination reaction was specific in 84.4 per cent of the cases. In the other seventy-nine cases an estimation of the specificity was impossible because clinical data were not given.

Tuberculosis and Function of Sex Glands.—Neurath shows curves which prove that, while the mortality from all acute infectious diseases is extremely low during the age of puberty, the mortality from tuberculosis increases greatly during this period and reaches its peak around the second decade of life. If different curves are plotted for the two sexes, it is found that in conformity with the earlier sexual maturation of women the mortality from tuberculosis rises earlier and reaches its peak sooner in women than in men. At the age of 20 the tuberculosis mortality of women is 10 per cent above that of men, at 27 the two curves cut each other, and after that the tuberculosis mortality of men remains slightly above that of women. Girls develop tertiary tuberculosis earlier than boys, and the author considers this a sexual manifestation. He points out further that in nurslings and small children tuberculosis becomes manifest mostly in the form of large inflammatory swellings of the bronchial lymph nodes and in a general tuberculosis or in metastatic foci, in children of school age generally in the form of small localized tuberculous infections of the bronchial lymph nodes with a good tendency to healing, but during the age of puberty true phthisis becomes frequent. These phthises are quite malignant and show only a slight tendency to heal. The fact that in a child, aged 5, who had pubertas praecox, a form of tuberculosis developed that ordinarily develops during the second decade of life, and the fact that castrated animals are less susceptible to tuberculosis, are further indications of a connection between the function of the glands and tuberculosis. On the one hand the susceptibility to tuberculosis is influenced by the sexual status, but on the other hand tuberculosis also influences the sexual sphere. In males atrophy and functional impairment of the gonads and specific tuberculous changes in the testicle and in the epididymis have been noted. In tuberculous females there may be amenorrhea. A contrast between the sexual function and tuberculosis is manifested in the frequently greatly increased libido of patients in the terminal stages of phthisis. Whether the pulmonary process causes this increase in the sexual urge, or whether the increased sexual activity hastens the development of the phthisis, cannot be stated.

Serotherapy and Prophylactic Vaccination for Scarlet Fever.—Mommsen points out that the characteristic of scarlet fever is not the presence of streptococci but rather the formation of streptococcic toxins and their invasion of the blood stream. The toxins are the precursors of the subsequent entrance of streptococci into the blood stream. The aim of the treatment should be to intercept and neutralize the toxins in order to prevent the development of a streptococcic sepsis. The antitoxic serum accomplishes this aim, provided it is given early enough and in sufficient quantities. Only the initial toxic stage is influenced by the serum. The author lists the different scarlet fever serums that are in use in Germany and indicates how much of each type is required in cases of average severity and in severe cases. He points out that the injection of horse serum is not an entirely harmless procedure and should be resorted to only when necessary. He discusses prophylactic vaccination for scarlet fever and states that the problem of active, prophylactic vaccination against scarlet fever has not yet been solved in an ideal manner. He considers this method still in the experimental stage and not yet ripe for general introduction in Germany. Moreover, he thinks that the present epidemiologic conditions require no such measure as prophylactic vaccination. He admits however that, if severe epidemics with a high lethality should develop, the threatened portion of the population should be subjected to prophylactic vaccination.

 *New Method of Treatment for Uremia. J. S. Schwarzmann.—p. 1381.

Effect of Foods with High Vitamin Content During Pregnancy.—Vogt observed that the administration of artificially produced vitamin A during pregnancy exerts no influence on the course of pregnancy, on the delivery, on the puerperium, on the development of the child or on lactation. However, the increase in the vitamin content of the food, particularly by the addition of cod liver oil, has a noticeable effect, especially on the development of the child and on the lactation capacity of the mother. The author stresses that during the entire period of pregnancy the diet should include an adequate amount of fresh fruits and vegetables. He observed that liver diet is helpful during pregnancy because of its high vitamin content and because it counteracts anemia.

New Treatment for Uremia.—Schwarzmann states that in experiments he observed that the tissue extracts reduce the rest nitrogen in the blood, the quantity of lactic acid and the acidity of the urine, and increase the reduced alkali reserve. From this he concluded that the reduction of dyspnea effected by the tissue extract is due to a reduction in acidosis. This factor induced him to try the tissue extracts in the dyspnea of patients with renal disease and in various forms of uremia. He states that uremic attacks in acute nephrosonephritis (with or without increase in the rest nitrogen), which are manifested by convulsions and loss of consciousness or headaches, nausea and vomiting, or headaches and frequent and deep respiration (Kussmaul's respiration), and finally uremic manifestations in patients with nephrosclerosis are favorably influenced by the injection of a tissue extract prepared from the skin, the pleura and the lungs. To a certain degree this extract is effective also in chronic azotemic uremia when the rest nitrogen is greatly increased. The author stresses that cessation of the attacks cannot have been simply accidental, for in all cases improvement concurred with administration of the tissue extract.

 Ileus As Result of Uterine Perforation During Abortion. W. Jelinek.—p. 2197.

Danger of Spinal Anesthesia in Cesarean Operation.—Franken points out that, although spinal anesthesia is the ideal method for gynecologic operations, it involves dangers when it is employed for cesarean sections. An investigation of the causes of the frequent complication and of the comparatively high mortality revealed to the author that there are two important factors: 1. If labor pains exist and the twilight sleep is not adequate, the woman, by her behavior, may force the anesthetic upward to the medulla oblongata. 2. The peculiar circulatory conditions of pregnant women and the action of spinal anesthesia on the circulation combine to constitute a grave danger. The author concludes that spinal anesthesia either should be entirely avoided in cesarean operations or, if it is not completely abandoned in this operation, the following precautions should be taken: 1. If a woman has uterine contractions, strains and is restless, spinal anesthesia should not be resorted to. 2. The dosage should be so low that the anesthesia reaches only to the umbilicus. 3. In cases presenting pathologically increased blood pressure and corresponding circulatory involvement, spinal anesthesia should be avoided, and whenever it is employed prophylactic circulatory measures should be taken.

THE TREATMENT OF CHRONIC ARTHRITIS

GENERAL PRINCIPLES

ERNEST E. IRONS, M.D.
CHICAGO

The treatment of chronic arthritis presents a problem that requires a radical revision of current medical opinion in regard to the nature of the disease, its importance as a major cause of suffering and disability, and the necessity of a wide-angled therapeutic attack. Conceptions of many diseases formerly thought of as disturbances of one organ of the body have been broadened by increasing understanding of their morbid anatomy and physiology to include the changes that inevitably involve other systems of the body. The profession has ceased to think of nephritis as a lesion of the kidney alone, or of cardiac disease as confined in its effects to the heart. Chronic arthritis can no longer be thought of as a disease of certain joints but rather as a systemic illness, in which there may be disturbances of the circulation, the general metabolism and nutrition and the gastro-intestinal system, as well as local changes in the joints.

Very early the only objective demonstrable disturbance may be in one or more joints. The immediate cause may be infection or trauma, which, however, becomes effective in producing serious disability because of the intrinsic qualities of the tissues of the patient. Successful therapeutic measures must therefore not only be directed at one single and perhaps immediate etiologic factor but planned to meet multiple causes active in each patient. This broader view of the nature and causes of arthritis is rapidly gaining ground in this country and Canada, largely through the efforts of the American Committee for the Study and Control of Rheumatic Diseases. It is proposed to consider here some of the facts that have led to the recognition of the importance of chronic arthritis as a disease of the body as a whole, the difficulties in attaining an orderly classification based on etiology, morbid anatomy or clinical course, and the necessity of therapeutic attack based on a well rounded conception of systemic effects as well as of local alterations in the joints.

DISABILITY CAUSED BY ARTHRITIS

The suffering and disability entailed by chronic arthritis exceed that from any other of the chronic diseases of temperate climates. A recent survey of

chronic disease in Massachusetts¹ showed that out of an estimated total of 500,000 persons afflicted with a chronic disease, of whom 225,000 were partially and 22,500 totally disabled, there were 138,000 persons ill with rheumatism, of whom 5,600 were totally disabled. The next most frequent cause of disability was heart disease with 84,000 and 2,600 totally disabled, followed by arteriosclerosis with 64,000, digestive diseases with 29,000, diseases of eye and ear with 24,000, apoplexy with 16,000, tuberculosis with 16,000, diabetes with 15,000 and cancer with 11,500.

The increase in average population age in Massachusetts is approximately 1 per cent with each decade. Falling birth and death rates also increase the proportions of persons who survive to the higher ages in which chronic diseases tend to increase. Similar surveys, if made in midwestern and western states, would probably yield somewhat lower figures for chronic diseases than in older populations in which larger numbers of persons have reached the higher age brackets.

Heart disease leads as a cause of death but, whereas the patient with heart disease lives from seven to nine years on the average, the rheumatic patient lives fourteen years or more. The mortality of chronic rheumatic disease is low, but the suffering and disability are enormous. Chronic arthritis offers a major challenge to the medical profession and the public.

Advances in the understanding of rheumatism are not unlike those which have evolved in other forms of disease. A century ago fevers were classified as intermittent, remittent and continued; many yielded to peruvian bark, others did not. Some were clearly identified with clinical disease entities such as yellow fever or pneumonia; others were ascribed to "phlegmasiae" or simply termed "idiopathic." With the discovery of the bacterial and protozoal causes of infections, fevers were rearranged and recognized as symptoms of underlying systemic disease, and treatment was placed on an etiologic basis.

Acute rheumatism was early separated clinically from chronic rheumatism and soon became distinguished as acute rheumatic fever; likewise gout was similarly set apart clinically. The arthropathies of neurogenic origin were recognized, and still later the identification of infections due to specific organisms such as the pneumococcus or gonococcus allowed the separation of acute and chronic arthritis associated with these infections.

There was then left the large group of cases of chronic arthritis, which Garrod in 1890 divided clinically into rheumatoid arthritis and osteo-arthritis. The view was frequently expressed then and in succeeding

Read before the Section on Practice of Medicine at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 14, 1934.

1. Bigelow, G. H., and Lombard, H. L.: *Cancer and Other Chronic Diseases in Massachusetts*, Boston, Houghton Mifflin Company, 1933.

decades that rheumatoid arthritis was more than a disease of joints and depended on underlying constitutional disturbances.

The application to chronic arthritis of the concept of focal infection under the leadership of Dr. Frank Billings made possible cures of metastatic joint infections, many of them so striking as to lead some observers to the conclusion that all chronic arthritis might be cured if only these patients were studied carefully enough to discover the hidden infection. Attention became centered on infection as a cause of chronic arthritis, frequently to the neglect of other or concomitant causes. General care of the patient, insisted on by Dr. Billings, was forgotten. The search for, discovery and treatment of hitherto unrecognized localized infection became a necessary routine in dealing with chronic arthritis, but it soon was evident that infection could account for but a part of the complex etiology of the disease.

During the same period of the past quarter century, advances in the study of metabolism, heredity, water balance and edema, of the functions of the thyroid and parathyroid glands and of the effect of nervous and vascular supply on nutrition of joints furnished clinical methods that were utilizable in the study of arthritis.

At this time came the World War, with the revelation of the large number of persons unfitted by physical disability for inclusion in the draft, the opportunities for study of arthritis under controlled conditions in groups of soldiers invalidated by reason of exposure, infections and trauma and finally the disclosures of health surveys, necessitated by national and local compensation laws, of the large numbers of persons in civil life who are partially or totally disabled by arthritis. Chronic arthritis has thus come to be recognized as a major cause of disability, with many possible causes which must receive adequate separate study in order that each patient may obtain a maximum benefit.

The removal of a focus of infection from some patients is sufficient to swing the balance toward recovery, and the natural recuperative powers determine healing of the arthritis. But there are many others in whom there is no evident remaining infection, and no amount of search for infection, nor attempts at immunization or desensitization, can be expected to benefit arthritis the continuance of which is dependent on dietary errors, on metabolic disturbances, on vascular abnormalities leading to malnutrition of cartilage, on nervous and trophic derangement or on hereditary or mechanical defects.

When an infection invades a previously normal knee joint the lesion may heal promptly without residual disability, or healing may be delayed. There is exudation, stimulation of connective tissue growth, pannus formation and erosion of cartilage; the joint surfaces are no longer in proper apposition, the blood supply is impaired so that healing is further interfered with, and the trauma of motion and weight bearing accentuate a process from which the initial active infectious cause may have abated or disappeared. It has been suggested that the extensive and progressive disorganization of joints with impaired function in some patients is due to inferior quality of cartilage, which is less able than the normal to withstand infection and injury or to participate in repair.

Any one of several causes may thus initiate the arthritis, but almost without exception other disturbances follow, so that in any patient with chronic

arthritis there are several determinants affecting the progress of the disease.

CLASSIFICATION

In a disease characterized by deformity of joints of varying clinical course, in the etiology of which such diverse elements as infection, trauma, glandular dyscrasias, hereditary inferiority of tissues, altered blood supply and the nutritional changes attendant on advancing age are concerned, it is evident that the first requirement for routine study is a workable classification.

Many attempts have been made to divide arthritis into groups on the basis of morbid anatomy, etiology or clinical course. After long consideration it was concluded by the American committee that, in the circumstances, a simple division of chronic arthritis into (1) chronic atrophic, rheumatoid arthritis and (2) chronic hypertrophic arthritis, osteo-arthritis, will serve best for the present.

The characteristics of atrophic arthritis are its incidence chiefly in younger persons of ptotic habit, especially women, multiple joint involvement with fusiform appearance of joints of the hands, often ulnar deflection, and later ankylosis. The onset is insidious or acute. In many patients, constitutional effects with slight fever, anemia and poor nutrition are evident.

Hypertrophic arthritis, osteo-arthritis, is found in persons at or beyond middle life, often well nourished, and produces disability varying from slight to severe crippling. It is usually polyarticular but may be monoarticular. Lipping of joints and hyperostoses are frequent; ankylosis is rare. Fibrous thickenings, Heberden's nodes, with later bony hyperplasia at the terminal joints of the fingers, are frequent. The effects of the trauma of work are often noted in the hands and spine of the laborer.

The committee of the British Medical Association has summarized its studies in an admirable report² in which is offered a somewhat more detailed subdivision of clinical and pathologic types. Both rheumatoid arthritis and osteo-arthritis are regarded as having two types, one with and a second without infection. There are added chronic villous arthritis, occurring mainly in women at the menopause, and spondylitis. Of the latter, two types are distinguished: (a) ankylopoietica in which the joints of the spine tend to fuse and in which infections as well as trauma are often concerned, and (b) osteo-arthritica, laborer's spine, in which the effects of wear and tear of hard work are evident and osteophytic outgrowths prominent.

The grouping of chronic arthritis into atrophic and hypertrophic should be regarded as tentative, to clarify discussion and facilitate clinical study. Some students of arthritis believe that the two groups represent clinically different diseases. Certainly the onset of disease in many patients with the atrophic type is associated with infections and, in many of those suffering from the osteo-arthritic, hypertrophic type, the anatomic alterations are clearly dependent on vascular and other tissue changes that characterize senescence. There are, however, borderline cases which it is difficult to place in one or the other group. Pathologic tissue changes characteristic of each group are sometimes found in the same patient, and roentgen films of some joints suggest the atrophic, while those of other joints, such as of the spine, suggest the hypertrophic type of arthritis. The

2. Causation and Treatment of Arthritis and Allied Conditions, Brit. M. J. 1:1033 (June 17) 1933.

kind of trauma and the location of the joint thus seem to determine in part the reaction that occurs.

Other clinicians, while admitting the desirability of a working classification of this sort, maintain that the pathologic and clinical differences between the two groups depend on the time of life when damage, whether due to infection, physical trauma or interference with nutrition, occurs, and on the kind of reaction to injury exhibited by the tissues of the individual patient. Gonococcic infection produces in one patient a quickly healing arthritis; in another, arthritis and tenosynovitis with limitation of motion from scar tissue and adhesions; in still another, a multiple arthritis which continues to progress to the clinical picture of advanced atrophic arthritis, or to the production of spondylitis ankylopoietica of the British classification.

The effect of age on the response of joints to injury is demonstrable in animals. Experimental ligation of the blood supply of the patella produces a hypertrophic type of arthritis in adult dogs but causes but little change in young dogs.³ Clinically, the hypertrophic type of chronic arthritis in man is more common in older persons, whereas the atrophic type appears in earlier decades of life. Again, in atrophic arthritis there is sometimes clearly evident a hereditary element, as shown by the incidence of arthritis in some families, as in grandmother, mother and daughter. Here is suggested a cartilage inferiority as regards healing and reaction to infection or trauma, analogous to family susceptibility or resistance to infectious diseases, to the early development of hypertension or to local tissue reaction in scars, in which in one person a cut of the skin heals with a slight scar and in another with an unsightly keloid.

In chronic arthritis one is therefore dealing with a disease which may be initiated by infection or trauma but the subsequent course of which is influenced by many conditions of individual and hereditary tissue peculiarity, age, and general and local nutrition.

The usual combinations of these conditions result in a disease that conforms clinically more or less closely to one or the other of the two great groups of atrophic or hypertrophic arthritis. It is to be noted that while such a division is extremely valuable clinically, it does not justify the assumption that one factor, such for example as infection, was or was not the precipitating cause of the disease years before. Infection may have initiated the process the later course of which is determined by the kind of response that the tissues are able to make by reason of their hereditary quality, vascular supply and exposure to further trauma.

Viewed in this way, the grouping of chronic arthritis into atrophic and hypertrophic is really a statement of how this or that patient has reacted to trauma involving his joints and is of value because it indicates the kind of problem, judging from previous clinical experience, he is likely to present in the future, as well as the difficulties he will encounter, and the measures to be taken to avoid them.

TREATMENT

The treatment of chronic arthritis consists in the removal or correction of such recognizable causes as may be found active when the patient comes for help, the prevention of mechanical defects and the correction of those already present, and the institution of

general measures to return the patient and his tissues to as normal a condition as possible. The patient and his disease are to be treated rather than his joints or one assumed etiologic factor alone. Successful management will depend on a highly individualized program, which ideally will meet the several requirements of each patient. Routine treatment of all patients by any one method cannot in the nature of the case succeed.

Before the several lines of therapeutic attack on chronic arthritis are considered, it is well to recall the natural history of the disease. In some patients the arthritis seems steadily to advance, but in the majority, especially the atrophic type, there are periods of spontaneous remission with improvement, which may last for months. Any harmless therapeutic measure, whether actually effective or not, will, if instituted at the beginning of a natural remission, be followed by improvement and thus be credited with a value it does not deserve. The conclusions of many studies of this or that method of treatment during the past quarter century are to a large extent invalidated by failure to take into account this tendency to remission in arthritis. Then, too, the assay of results of therapeutic measures must include subjective as well as objective elements. The report of a patient as to how he feels is influenced to a considerable extent by his state of mind, whether of hope or discouragement.

INFECTIONS

Infections frequently mark the onset of arthritis, which is destined to progress into a chronic disease. The recognition of chronic focal infection as a cause of disease of the joints is one of the great advances in medicine of this century, and the treatment of chronic arthritis properly includes a search for and eradication of chronic infections. Operations for the removal of infections obviously should be planned to avoid shock to the patient. Sometimes removal of infection will suffice to swing the balance in favor of the patient, and his recovery is assured. More often, however, infection is only one, though possibly the precipitating, factor in a process that is continued by one or usually several other factors. Here dependence on measures directed toward the infection alone will obviously result in failure. The importance of underlying hereditary and general influences is emphasized when one recalls the high incidence of focal infections in persons who do not suffer from arthritis or other demonstrable organic disease.

It is not within the scope of this paper to review the many reported results of the removal of infections in chronic arthritis. Two recent reports, however, exemplify some of the etiologic and therapeutic relationships already cited. Stainsby and Nicholls⁴ treated rheumatoid arthritis by removal of the tonsils and by vaccines. Of twenty patients treated by tonsillectomy alone there was improvement in 60 per cent; of eighty-three patients treated by tonsillectomy and vaccines there was improvement in 57.8 per cent; of 194 treated by vaccine alone there was improvement in 35.6 per cent. Miltner and Kulowski⁵ found that the benefit of the removal of focal infections in chronic arthritis depended on age, type of disease and its duration. Of thirty-three patients with atrophic arthritis under 16 years of age, 73 per cent were cured and 16 per cent

3. Goldhaft, A. D.; Wright, L. M., and Pemberton, Ralph: The Influence of Age in the Experimental Production of Hypertrophic Arthritis, *Ann. Int. Med.* 6: 1591 (June) 1933.

5. Miltner, L. J., and Kulowski, Jacob: *J. Bone & Joint Surg.* 15: 383 (April) 1933.

improved. Of sixty-three patients over 16 years of age, 15 per cent were cured and 58 per cent improved. Of 100 patients with hypertrophic arthritis, 95 per cent showed demonstrable foci, dental foci predominating, but in only 9 per cent was there marked improvement following their removal.

These and other studies indicate that infection is a larger contributory element in the continuation of the atrophic than of the hypertrophic group. There is diversity of opinion, based on the results of blood cultures, as to the incidence and significance of bacteremia in chronic arthritis, but most investigators have found bacteria in cultures of the blood in a larger proportion of patients in the atrophic than in the hypertrophic group. Whatever may be the final conclusion as to this controversial matter, as well as to the significance of streptococcus agglutinins, it seems quite possible that in chronic arthritis the finding of bacteria in the blood may be of greatest importance as an indication of lowered humoral and cellular resistance incidental to the general disease. Bacterial invasion of joints may occur early and be of primary etiologic importance but conceivably may follow later under conditions of lowered resistance in a patient whose arthritis originally resulted from a combination of other causes.

ALLERGY

Evidence is growing that part of the symptoms of recurrent joint pain and swelling may be due to an allergic response of sensitized joint tissues rather than to actual new lodgment of bacterial bodies. Both experimental and clinical observations suggest an analogy between the urticaria and rashes of serum disease and the shifting swelling, redness and pain of the joints in acute rheumatic fever. Likewise in chronic recurrent iritis many facts favor the view that some recurrences are due to reactions of the uveal tract previously sensitized by infection, through the renewed invasion of the ocular tissues, not by bacteria but by proteins possibly of bacterial origin. Applying this concept to chronic arthritis, exacerbations of joint swelling and pain may thus result from superficial mucosal infections such as result from minor colds. The cause of the exacerbation may thus be infectious but not associated with any hidden or deep seated removable infection. Patients in whom there remains no demonstrable focus of infection frequently suffer from recurrence of arthritis following acute respiratory infections and colds.

Freedom from exposure to streptococcal infections, as demonstrated by Coburn in the treatment of patients with rheumatic fever by their removal to Puerto Rico, where streptococcal infections are rare, and the favorable effect on patients with chronic arthritis and chronic sinus infections of a sojourn in the dry climate of the Southwest emphasize the importance of preventing renewed exposure to superficial infections. Prevention here consists not in renewed search for hidden foci but in decreasing the probabilities of exposure to infection and in improving general nutrition and resistance.

VACCINES

Treatment by the injection of vaccines, usually of streptococcal origin, is widely practiced, and undoubted instances of improvement under this treatment have been reported by excellent observers. It must be evident however that, in a disease in which in each case several causes are almost always active, dependence on one method alone results in the neglect of other pro-

cedures of equal importance to the welfare of the patient and, if vaccines are used in combination with other necessary methods, much caution is needed in evaluating the contribution of vaccines to the improvement. Too often in the past the natural history of arthritis with its spontaneous periods of remission and exacerbation has been forgotten.

GENERAL MANAGEMENT

With the conception of chronic arthritis as a disease affecting the entire body rather than the joints alone, the plan of treatment at once is broadened and individualized for each patient. There is no single accepted or acceptable method of treatment of chronic arthritis. It is here possible only to refer to general principles.

Early recognition and treatment of the condition that threatens the patient offers the greatest hope of reducing invalidism from this cause in years to come. In patients first seen when the disease is more advanced, much can still be done to prevent deformity and ankylosis, and, if ankylosis seems inevitable, to maintain the joints in the most useful functional positions.

In atrophic arthritis the restoration of general nutrition is of first importance and is often extremely difficult, requiring for its attainment relief from pain, relative or complete bed rest, and removal of sources of nervous irritation and worry, in addition to a balanced diet.

The diet should be appetizing and include an abundance of vegetables and fruit, protein and fat. Food idiosyncrasies, if present, must be considered in arranging the dietary. Long illness and poor appetites often lead patients to take habitually an excess of concentrated carbohydrates, and lack of exercise further interferes with carbohydrate and other metabolism. Pemberton has found that decrease in carbohydrates with increase in proteins and fats favors reduction in joint swellings. The replacement of concentrated carbohydrates with protein, fat, vegetables and fruits increases the vitamin content of the food and supplies a residue that aids in the correction of the tendency to bowel atony and constipation.

The administration of small doses of thyroid substance sometimes stimulates the appetite, increases the sense of well being of the patient and, when hypothyroidism is present, may contribute to resistance to infection. Anemia often requires the reinforcement of the diet with iron. Although many patients with atrophic arthritis are underweight, some tend to become fat, especially if they are confined to bed, and here the diet, particularly the carbohydrates, must be reduced. In hypertrophic arthritis occurring in patients with a tendency toward overweight or obesity, reduction in carbohydrates and in the total diet contributes to general improvement as well as to reduction of the load on weight-bearing joints. The relief of pain by suitable analgesics such as those of the salicylic group is necessary for the comfort of the patient. The dangers of the use of a number of newer drugs, such as cinchophen for long periods, have been demonstrated by the tragic experiences of recent years.

Referred pain, arising from pressure or irritation of spinal nerves in osteo-arthritis, and requiring careful study to distinguish it from pain originating in the heart, abdominal viscera or peripheral nerves, is often relieved by intelligent application of corrective orthopedic measures.

The benefits of orthopedic measures to correct deformities and increase the functional usefulness of

joints are not confined to the joints. The patient, bed-ridden until the contractures of the knees were corrected, is now able to walk and take exercise, has an improved appetite, assimilates food better and, most important of all, has now a hopeful instead of a hopeless attitude toward life.

Physical therapeutic measures to improve circulation and local nutrition by massage, heat cautiously applied in suitable cases, exercise in the main active rather than passive, and heliotherapy, natural and artificial, may be applied to meet the special conditions in each case.

SUMMARY

Arthritis is a major cause of suffering and disability, and it entails economic distress greater than that of any other disease in temperate climates. The several factors concerned in the onset and continued course of chronic arthritis include infection, trauma, interference with normal blood and nerve supply, hereditary cartilage and tissue inferiority, and general causes such as fatigue, exposure, nervous strain, general malnutrition and glandular dysfunction.

Chronic arthritis is to be thought of as a disease that affects the body as a whole rather than the joints alone. For clinical purposes this disease is divided into two groups, atrophic or rheumatoid arthritis, and hypertrophic arthritis or osteo-arthritis, although it seems possible that these types often represent the results of similar series of events in persons of different ages and intrinsic qualities of tissues.

Treatment must be highly individualized to meet the several requirements of each patient. The employment of one method of treatment for all patients, in a disease whose etiology and course vary with each patient, seems unwarranted. There is also the danger that relatively minor procedures such as some dietary, physical therapeutic or other measures, perhaps valuable in themselves, may be unduly stressed in the clinic so that patients are given an erroneous impression of their importance. Here as elsewhere in medicine there is constant need of rugged honesty, both moral and intellectual, and sincerity of purpose.

Treatment based on the broader conception of chronic arthritis as a general disease will meet the requirements of a larger number of patients, and the percentage of cures or marked improvement will be increased. While a spirit of optimism is necessary in this difficult field, it must still be recognized that there will be some patients whose disease is far advanced for whom but little can be accomplished. The number of these will be materially decreased as adequate broad visioned treatment is instituted at an earlier stage, before irreparable damage has been done.

1758 West Harrison Street.

Invention of Histologic Technic.—In 1835 Purkinje, an Austrian priest of Gipsy family, became possessed of a microscope. In a short space of time he had discovered the nerve cell, and this discovery, added to that of Gall of the nerve tract, was the instigation of all later work. He had invented a hardening reagent, bichromate of potash, which would allow sections of soft tissue to be cut; a machine, the microtome, to cut the sections; a stain, carmine, which would bring out the details; a clarifying reagent, oil of cloves, which would make microscopical examination possible; and a method of making permanent preparations with Canada balsam. Purkinje's work was epoch making in the progress it caused.—Collier, James: The Harveian Oration on "Inventions and the Outlook in Neurology," *Brit. M. J.* 2:707 (Oct. 20) 1934.

THE MEDICAL TREATMENT OF CHRONIC ARTHRITIS

RUSSELL L. CECIL, M.D.

NEW YORK

It is customary nowadays to open any discussion on the treatment of chronic arthritis with a preliminary paragraph on the classification of the disease. This is a rational procedure, but unfortunately the terminology now in use is confusing to many physicians, chiefly because of the multiplicity of synonyms. Many of these synonyms might well be forgotten. As a matter of fact the modern classification of chronic arthritis is quite simple, much simpler than that of chronic nephritis or chronic heart disease. The differentiation of chronic arthritis into two groups has resulted largely from careful pathologic studies of the disease, but there are definite clinical features of each type as well.

Pathologically the two great groups are so different that it is hard to see how any one could confuse them. Osteo-arthritis, or hypertrophic arthritis, is well named, because it is a degenerative process which affects the bone and cartilage. The term hypertrophic arthritis is also appropriate because of the hypertrophic changes that take place in the bone around the margins of the articular surface. Pathologists look on osteo-arthritis as a senescent process similar to arteriosclerosis or gray hair. Keefer and Myers¹ have recently shown that these degenerative changes in the joint are present in a high percentage of old people who come to autopsy after death from some other malady. In other words, hypertrophic arthritis is hardly a disease but a natural biologic process and simply one phase of senescence. The Germans and French often speak of this condition as an "osteo-arthritis," a term which would indicate that it is not inflammatory in nature. Hypertrophic arthritis is characterized by some enlargement of the ends of the bone and by an absence of soft tissue swelling. Ankylosis does not occur in this form of arthritis.

Rheumatoid arthritis, or chronic infectious arthritis, is a chronic progressive inflammatory disease, characterized in its early stage by migratory pain and swelling in various joints and in the later stages by ankylosis and deformity. Because of its capacity to cripple, it presents one of the great public health problems of civilization. The belief is quite general that rheumatoid arthritis is a chronic infection, and there are a considerable number who look on it as a chronic streptococcal infection. In contrast to hypertrophic arthritis, the joints in rheumatoid arthritis usually show soft tissue swelling.

If one limits oneself to the aforementioned terms, it would seem that the differentiation between these two types of arthritis is simple enough. It must be admitted, however, that there does exist a so-called mixed type of arthritis in which in addition to soft tissue swelling of one or more joints, definite changes in the bone and cartilage are also present. The existence of this mixed type leads Rigler and Wetherby,² and more recently Archer,³ to conclude that hypertrophic

Read before the Section on Practice of Medicine at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 14, 1934.

1. Keefer, C. S., and Myers, W. K.: The Incidence and Pathogenesis of Degenerative Arthritis, *J. A. M. A.* 102:811 (March 17) 1934.

2. Rigler, Leo, and Wetherby, Macnider: Roentgen Findings in Chronic Polyarticular Arthritis, *Am. J. Roentgenol.* 29:766 (June) 1933.

3. Archer, B. H.: Chronic Nonspecific Arthritis, *J. A. M. A.* 102:1449 (May 5) 1934.

and rheumatoid arthritis are "different manifestations of the same disease." If this were the case, there would certainly be little reason for classifying chronic arthritis at all. This confusion, which exists in the minds of some, results, I believe, from inadequate study of the life history of the two diseases. If, as already pointed out, hypertrophic arthritis is present in almost a hundred per cent of elderly patients, it is hard to see how it could have any possible connection with rheumatoid arthritis, which usually appears in the earlier decades of life and which, in its incipient stage, is purely a synovial disorder characterized by no changes whatever in the bone or cartilage. Archer finds it difficult to understand how a patient could have a Heberden's node (of hypertrophic origin) on one joint and a rheumatoid enlargement of another joint on the same finger or even on the same hand. However, there is nothing to prevent a gray-haired old man from contracting an infectious seborrhea, and there is no reason why an old woman with Heberden's nodes should not contract an infectious arthritis, provided she has a focus of infection and her general resistance becomes sufficiently lowered. In other words, what has the existence of Heberden's nodes to do with contracting an infectious disease, whether it is tuberculosis or rheumatoid arthritis?

But there is another phase to this question of so-called mixed arthritis, a term, by the way, which seems to me unnecessary. It is a well known fact that any chronic irritation in a joint, if maintained long enough, will eventually lead to hypertrophic changes in the bone. This has been demonstrated repeatedly on animals by injection of sand and other foreign material into the joint cavity. Fractures that involve the articular surface of a bone often lead to subsequent hypertrophic changes in the joint, regardless of the patient's age. One of the commonest of all irritants is infection. Any chronic infection of a joint may lead, in the course of time, to more or less hypertrophic change in the joint affected. For example, both gonococcal arthritis and tuberculous arthritis may lead eventually to hypertrophic bony changes. This is no reason, however, for calling gonococcal arthritis and tuberculous arthritis "different manifestations of the same disease." Rheumatoid arthritis, like other infections of the joints, is no exception to this rule. Starting as an inflammation of the synovial membrane, the original infection may be complicated finally by osteo-arthritic manifestations.

The time to determine the nature of a morbid process is in its incipience. In the late stages of any chronic disease the picture becomes so blurred by many complicating factors that the real character of the pathologic process is readily obscured.

TREATMENT OF HYPERTROPHIC ARTHRITIS

If, as I have already stated, hypertrophic arthritis is a senescent lesion, one cannot hope to cure it in the real sense of the word. Fortunately many individuals with this type of arthritis do not need a cure, because they have no symptoms. Symptoms develop when a hypertrophic or "worn-out" joint is subjected to acute or chronic trauma. This trauma is referable in many cases to overweight, especially when the symptoms occur in the weight-bearing joints. However, the trauma may result from many other causes, such as occupation, bad posture and deformities. The obvious method of treating this condition, therefore, is first to remove the cause. The patient cannot be cured of his senescent joint

changes, but he can often be relieved of his symptoms if the proper therapeutic measures are employed.

First, then, under the medical treatment of hypertrophic arthritis is removal of the source of trauma to the affected joint. When the symptoms are in the knees, the condition can usually be traced to overweight. There is one special type of hypertrophic arthritis that is seen very frequently in the clinic. A middle-aged woman, considerably overweight, comes in complaining of pain and stiffness in the knees, Heberden's nodes on the fingers and often pain and stiffness in the lumbar spine. This syndrome appears so frequently at the time of the menopause that it has been called menopausal or climacteric arthritis. These patients are often greatly relieved by the simple expedient of reducing the weight from 20 to 25 pounds (9 to 11 Kg.) by means of a low calory diet. If the basal metabolism rate is below normal, thyroid extract can be administered with benefit.

The next most important phase of the treatment of hypertrophic arthritis is cessation of overactivity of the joint. By this I do not mean complete rest or immobilization but considerably less exercise than the patient has been accustomed to take. Many of these middle-aged or elderly patients are convinced that excessive exercise is the road to cure, not realizing that the relief they obtain from exercise is only temporary and that the joint is being subjected to additional injury by such measures.

This type of obese middle-aged patient usually suffers from constipation and the intestinal tract should receive attention. There is nothing better in my opinion than the well known combination of agar and liquid petrolatum. Sometimes a roughage diet consisting chiefly of fruits and vegetables will answer the purpose.

Many patients with hypertrophic arthritis get relief from a visit to one of the spas. Rest, relaxation and possibly the copious drinking of water do as much for the patient as the baths and physical therapy.

Drugs are of very little value in this form of arthritis. Salicylates can be employed to relieve pain, and iodides are said to be helpful in some cases.

Heat in all its forms is extremely valuable and is discussed by Dr. Loring T. Swaim under the heading of "The Orthopedic and Physical Therapeutic Treatment of Chronic Arthritis."

TREATMENT OF RHEUMATOID ARTHRITIS

Rheumatoid arthritis is one of the great diseases of medicine. The etiology of this arthropathy is still under debate and cannot be discussed at length in this paper. Suffice to say that rheumatoid arthritis has a specific pathology and a characteristic syndrome, and that in most quarters it is looked on as a chronic infection. A good deal of work has been done on the bacteriology of rheumatoid arthritis, and a number of investigators have succeeded in recovering streptococci from the blood and joints of patients suffering from this disease. Other bacteriologists have failed entirely in their attempts to recover streptococci from the lesions of rheumatoid arthritis. This discrepancy in results is difficult to explain but is possibly referable to minor differences in culture mediums. Some have suspected that the streptococci in question were contaminations from the air or skin, but it is hard to reconcile such a theory with the carefully controlled studies of Callow,⁴ who found streptococci in the blood of a high percentage

4. Callow, B. R.: Bacteriologic Investigation of the Blood in Rheumatic Fever, *J. Infect. Dis.* 52: 279 (May-June) 1933.

of patients with rheumatic fever. Callow's studies were carried out under the direction of William H. Park, who presumably would have recognized contaminations as such. If time and space permitted, other evidence such as the presence of specific streptococcus agglutinins and precipitins in the serums of rheumatoid patients could be cited in support of the streptococcic origin of rheumatoid arthritis.

If current ideas about the infectious nature of rheumatoid arthritis are correct, the treatment of this disease should be quite different from that which has just been outlined for senescent osteo-arthritis. In the latter condition the elimination of trauma and stimulation of the local circulation are the important factors. If, however, in rheumatoid arthritis one is dealing with a chronic infection, the therapeutic approach should be similar in a general way to that which would be taken toward any other chronic infection. Unfortunately the treatment of rheumatoid arthritis suffers for lack of standardization. Stokes and his associates⁵ recently published an article on the "standard treatment" of syphilis. A similar article could be written on the standard treatment of tuberculosis. It would be very difficult, however, to write an article on the standard treatment of rheumatoid arthritis for the simple reason that there is no standardized therapy for this disease. I have often thought that it would be an interesting experience for an arthritic patient if he should start in Boston and make a circuit of the United States and Canada, taking the treatment for his disease in various medical centers as it was prescribed by the leading authorities in those communities. In some places focal infection would be stressed. In other clinics he would receive vaccine. In still others he would be put on a rigid dietary regimen, and finally he might receive physical therapy and orthopedic treatment.

In order to get some general idea as to how the various forms of treatment for rheumatoid arthritis should be rated, I recently sent a questionnaire to sixteen of my friends in various parts of America who are interested in rheumatoid arthritis. With one or two exceptions, these men are professors in leading medical schools and all of them have an excellent background in the handling of arthritic patients. In the questionnaire I asked these physicians to rate by number the importance of the following methods of treatment:

- Blood transfusions.
- Climate cure.
- Foreign protein therapy.
- Hydrotherapy.
- Hyperthermia.
- Intestinal hygiene (including colonic irrigations, purgatives and the like).
- Low carbohydrate diet.
- Drugs.
- Physical therapy (including massage and exercise).
- Removal of foci of infection.
- Rest.
- Streptococcus vaccine.

The sixteen physicians were also asked to make any comments that occurred to them concerning these various forms of treatment. I realized, of course, that this was a very artificial method of getting at the relative merits of twelve different forms of therapy, but it occurred to me that by means of such a questionnaire

I might be able to draw certain conclusions concerning the trend of modern therapy in rheumatoid arthritis.

The answers were interesting and fulfilled very well the purpose of the questionnaire. The results ran about as follows:

Blood transfusions did not evoke much enthusiasm. None of the voters rated them high on the list. Several remarked that they were useful in patients with marked anemia.

The climate cure got a much better reception. It was given honorable mention (first, second or third place) in five out of the sixteen questionnaires. Several voters mentioned the fact that a dry hot climate, such as that of Arizona or New Mexico, is especially good for arthritic patients who are also suffering from sinus infection.

Foreign protein therapy got a very lukewarm response. None of the voters placed it high on the list, though one physician remarked that typhoid vaccine was his favorite treatment in active cases. The general reaction to foreign protein treatment was that it was a rather highly specialized form of therapy for special cases.

Hydrotherapy received only one vote in the first three places, and the general opinion was that it was of value chiefly in the relief of symptoms.

Hyperthermia by means of the "short wave" or diathermy elicited very little enthusiasm. One physician remarked that there was no theoretical basis for it, as it would deplete an already ill patient rather than build him up.

Intestinal hygiene, including colonic irrigations, purgatives and so on received only one honor vote, and this was third place. One physician writes "I feel convinced that if one attended to intestinal hygiene *per se* he would get nowhere, unless under intestinal hygiene the concept of a proper diet was included." Another voter aptly remarks "One should pay the same attention to intestinal hygiene in the arthritic as in any other ill patient."

A low carbohydrate diet received fairly enthusiastic support, getting "honorable mention" in five out of sixteen questionnaires, though it did not receive first place in any of the lists.

Drugs did not receive honorable mention in a single questionnaire. One doctor writes "Drugs should be considered a very minor aspect in the treatment of arthritis." Iron of course was mentioned frequently as indispensable for secondary anemia. All agreed that salicylates were of value only for their analgesic effect.

Physical therapy, including massage and exercises, received on the whole rather enthusiastic support, getting honorable mention in eight out of sixteen questionnaires. Even here, however, there were skeptics. One voter writes "No results after large experience." Another writes "Physiotherapy may give symptomatic relief but is not a cure. With some patients the fatigue following treatment does more harm than good."

Removal of foci of infection is evidently a popular therapeutic measure, as it received "honorable mention" in eleven of the sixteen questionnaires. In seven questionnaires it received first place, in three second place and in one third place. Several voters, however, stressed the apparent futility of removing foci of infection late in the course of the disease.

Rest received the highest number of "honors." Twelve out of sixteen voters gave it honorable mention,

and in seven questionnaires rest received first place. Several physicians stressed the importance of mental as well as physical rest.

Streptococcus vaccine, either stock or autogenous, met with only moderate enthusiasm. It received honorable mention in five out of sixteen questionnaires. Some of the voters were frankly skeptical concerning its beneficial effects. Others felt that whatever virtue resided in streptococcus vaccine was nonspecific in character.

Summarizing, then, it may be said that this questionnaire, though admittedly a very rough gage, brought out the following facts: Apparently the most popular therapeutic measures at present in vogue in the treatment of rheumatoid arthritis are rest, removal of focal infections, and physical therapy. Climatotherapy is also held in considerable esteem, while a low carbohydrate diet and streptococcus vaccine both received a fair amount of recognition. Through an oversight, vitamins were not listed in the questionnaire, but a number of physicians, in discussing diet or medication, spoke of vitamins as an important part of their treatment of rheumatoid arthritis.

AUTHOR'S METHOD OF TREATMENT

My own method of treating rheumatoid arthritis is based on experience that has come from the handling of these patients in the outpatient clinic, in the hospital ward, and in private practice. The treatment differs somewhat with the duration of the disease and the degree of its activity. As a matter of convenience in discussing the therapy of this disease, the cases may be divided roughly into four groups, representing four different stages or aspects of it:

1. Mild early cases.
2. Active febrile cases.
3. Well established chronic cases.
4. Advanced bedridden cases.

GROUP 1.—Mild Early Cases (from three to eighteen months' duration).—This type of rheumatoid patient is usually seen first in the outpatient clinic or in office practice. The patient is often a young adult, though he may be of any age. The disease is still in its early phases and the cartilage of the joints has suffered little or no injury. The symptoms are mild and the disease is running a sluggish course. There may be several fusiform fingers, one or two swollen knuckles, discomfort in the wrists and often swelling or pain in the knees or ankles. None of the joints show ankylosis or deformity.

The diagnosis is based on the clinical picture, an accelerated sedimentation rate of the red blood cells and often a slight increase in the immature cells of the blood. About 60 to 70 per cent of these early cases will show specific agglutinins for *Streptococcus hemolyticus*.

(a) **Foci of Infection:** The therapeutic procedure that I consider of first importance in this type of case is the removal of focal infections. If the tonsils appear to be infected, or even if they are under suspicion and if the patient is under 50 years of age, a tonsillectomy will probably be recommended. It has been learned from experience to distrust all tonsils. I am much more conservative in my attitude toward devitalized teeth and rarely advise their extraction unless there is definite evidence of periapical infection. In respect to sinuses, the advice of a good laryngologist is sought, preferably one who is not too radically minded, and I am very prone to follow his advice with regard to the treatment

of whatever sinus infection exists. The possibility of infection in the genito-urinary tract and other parts of the body is also eliminated.

A great deal of success in the treatment of focal infection depends on who removes the focus. A tonsillectomy performed by a clumsy operator is more apt to bring on an exacerbation of joint symptoms than it is to cure the patient. I believe that it is better treatment to remove the focus and then build up the patient than it is to build up the patient and then remove the focus.

(b) **Rest:** I agree with the physicians who answered the questionnaire that rest is a very vital part of the treatment of rheumatoid arthritis. In this ambulant type of case, however, rest is a difficult form of therapy to enforce, chiefly because the patient, whether man or woman, is anxious to keep up the daily routine of duties. If these patients in the early stages of rheumatoid arthritis can be persuaded to give up work and take a rest cure for from six months to a year, a much higher percentage of them would make a complete and permanent recovery. As it is, and chiefly perhaps because of economic reasons, the physician must compromise on the rest issue, and the patient is advised to take from one to two hours' rest in bed every day after lunch. If a real rest cure can be taken away from home, it is far preferable, because the patient gets a mental and emotional rest as well as a physical one.

(c) **Vaccine:** Most rheumatoid patients in this early group receive streptococcus vaccine intravenously. The vaccine is a stock hemolytic streptococcus vaccine, prepared from several "typical strains" recovered from the blood and joints of patients with rheumatoid arthritis⁶ and all of which are agglutinated by the serum from rheumatoid patients. I have no intention of giving up streptococcus vaccine in the treatment of rheumatoid arthritis because of a certain reaction that exists now in various quarters against its use. I have seen too many patients improve under this form of treatment to question its value in a considerable number of cases. No doubt vaccine therapy has been abused, chiefly by those clinicians who have given vaccine and ignored other important phases of the treatment; but *Streptococcus hemolyticus* vaccine given in small doses by the intravenous route seems to me to have a definite place in the therapy of rheumatoid arthritis.

The streptococcus vaccine, as it is employed, is made up in various dilutions for intravenous therapy. Dilution 1 contains 1 million streptococci to 1 cc. of vaccine. Dilution 2 contains 10 million streptococci to 1 cc. Dilution 3 contains 100 million streptococci to 1 cc., and dilution 4, 1,000 million. The first dose is usually 0.05 cc. of dilution 1 (50,000 streptococci) intravenously. Each succeeding dose is increased by 0.05 cc. When a dosage of 1 cc. has been reached, treatment with dilution 2 is started with 0.1 cc., and the dosage increased by 0.05 cc. with each injection, and so on through dilution 3.

If for any reason the intravenous method is contraindicated, the subcutaneous route can be used. For this method, *Streptococcus hemolyticus* vaccine contains one billion streptococci to each cubic centimeter of vaccine. The first dose is 0.05 cc. Each succeeding dose is increased by 0.05 cc. but rarely exceeds 1 cc.

6. Cecil, R. L.; Nicholls, Edith E., and Stainsby, W. J.: The Bacteriology of the Blood and Joints in Chronic Infectious Arthritis. *Arch. Int. Med.* 43: 571 (May, 1929); The Etiology of Rheumatoid Arthritis, *Am. J. M. Sc.* 181: 12 (Jan.) 1931.

In both the intravenous and the subcutaneous method the interval between doses should be from four to five days. If the patient has a severe local or mild general reaction with definite increase of joint pain following the injection, the previous dose of vaccine is repeated or the amount reduced. A large part of the success in vaccine therapy depends on the persistence with which it is prosecuted. As a rule, very little benefit can be expected during the first two or three months of treatment. The injections should therefore be continued for at least three or four months.

It is very important in using streptococcus vaccine to avoid overdosage, especially when the intravenous method is employed. An overdose of foreign protein or typhoid vaccine may cause a chill and fever and still react favorably on the patient's symptoms. On the other hand, an overdose of streptococcus vaccine by the intravenous route may bring on an acute and sometimes a severe exacerbation of symptoms in the joints. Episodes of this kind probably have an allergic basis. It seems likely that whatever virtue streptococcus vaccine has in rheumatoid arthritis is more in the nature of a desensitizing function than an immunizing one.

(d) **Drugs:** Drugs play a comparatively minor part in the treatment of rheumatoid arthritis. The few that I do use, however, are important. Iron in the form of ferric ammonium citrate or reduced iron is valuable in counteracting the secondary anemia, which is so common in this disease; and arsenic seems to have a beneficial effect in many cases. One is very prone to use both of these drugs in treating early ambulant cases. I have been quite disappointed in the results obtained from various forms of sulphur and the various preparations of iodine that have been recommended. The salicylates of course are helpful in relieving pain but have no specific effect on the course of the disease.

My experience with gold salts in the treatment of rheumatoid arthritis has been rather limited. However, the results reported by Forestier⁷ in France and by Slot and Deville⁸ in England are very encouraging. Forestier considers sodium gold thiopropanol sulphionate the best chemical agent for the treatment of rheumatoid arthritis. Slot and Deville assert that in rheumatoid arthritis the results of gold therapy are superior to those of all other methods of treatment. In their opinion gold therapy marks a distinct advance in the treatment of this disease. Patients whom I have treated by this method have never shown very striking results. Perhaps a larger experience with gold therapy, however, might change my opinion.

(e) **Low Carbohydrate Diet and Vitamins:** Practically all of my patients in this group of early mild cases are put on a low carbohydrate maintenance diet, which is reinforced by a vitamin program. The vitamins usually employed are (1) vitamin A in the form of concentrated cod liver oil (or haliver oil), preferably in capsules, (2) vitamin B in the form of brewers' yeast or some of the specially prepared forms of wheat germ such as embo or bemax, (3) vitamin C as orange juice and tomato juice, and (4) vitamin D in the form of viosterol. This is taken in capsules with the cod liver oil. It must be acknowledged that this form of therapy is largely empirical, though the studies of Fletcher⁹

would indicate that vitamin B has value in correcting the atony of the colon, which is so frequently seen in chronic arthritis; and more recently the studies of Rinehart¹⁰ would indicate that a vitamin C deficiency might have some relation to rheumatoid arthritis. Rinehart has shown that joint lesions with a pathologic condition quite similar to that of rheumatoid arthritis can be produced in guinea-pigs that have been subjected to a vitamin C deficient diet and then injected intracutaneously with virulent streptococci.

(f) **Elimination:** I believe in elimination through the bowels, the bladder and the skin, but of the three elimination through the intestinal tract is the most important. Agar and liquid petrolatum are excellent for obtaining regular bowel movements, but in some cases more drastic measures may be necessary. I have seen very few patients benefited by colonic irrigations.

(g) **Baths:** Much has been written about baths of every kind in the treatment of rheumatoid arthritis, but the significant factor in all of them is probably heat. I recommend hot baths to all patients with rheumatoid arthritis as one method of giving them temporary relief of symptoms. It is not generally realized that several degrees of fever can be readily produced in a patient by the use of a very hot bath. The formula that I use is as follows:

BATH FORMULA

The tub is filled with hot water at a temperature of about 100 F.

The patient gets in the bath, and the temperature of the bath is gradually raised to 104 F.

The bath is maintained at this temperature by means of a bath thermometer, and the patient remains in the bath, submerged up to the neck, for from thirty to forty-five minutes.

A cold wet towel can be applied to the forehead to lessen the discomfort.

The patient should then be sponged off with cold water or alcohol and go to bed.

This bath should be taken on an empty stomach. The patient can take some food, preferably liquids, after the bath is over.

(h) **Physical Therapy:** Under physical therapy are included heat in various forms, massage and active and passive exercises. Most patients with rheumatoid arthritis feel better when the painful joints are subjected to heat, but this is not a universal experience. In some instances the pain is actually increased by the application of diathermy or infra-red rays. The value of physical therapy and the various forms of exercise are discussed in detail by Dr. Swaim.

(i) **Climate:** I believe in the beneficent effect of a warm dry climate with minimal barometric variations. Holbrook¹¹ has recently written an interesting and helpful article on the treatment of rheumatic arthritis and in this article he discusses climatic therapy at considerable length. I agree with Holbrook's statement that the various forms of heliotherapy constitute the major portion of specific climatic therapy. Unfortunately, a comparatively small number of rheumatoid patients can afford to make the pilgrimage to the Southwest, and those who cannot take advantage of that climate should have as much exposure as possible to sunlight at home.

(j) **Psychotherapy:** Most patients with rheumatoid arthritis suffer a great deal from mental depression and consequently need an abundant measure of psychother-

apy. On the other hand, there are some individuals, usually men, who do not take their affliction seriously enough and the physician in all fairness to the patient should make clear to him the serious potentialities of the disease. The small, slender type of neurotic woman is particularly susceptible to rheumatoid arthritis and often responds poorly to treatment. It is this type of patient that needs the greatest amount of moral encouragement. Unless the physician makes very earnest efforts along this line he will fail to get the full cooperation and confidence of the patient, factors that mean much in the stubborn fight against the disease.

GROUP 2.—The Active Febrile Cases.—These patients are usually seen at home or in the hospital. They have a fever which may amount at times to a rise of several degrees Fahrenheit. Several joints, usually including one or both knees, are swollen, hot and painful. Some of these cases might easily be mistaken for rheumatic fever were it not for the absence of cardiac symptoms and their failure to yield to salicylates. In some instances, rheumatoid arthritis is ushered in with active febrile symptoms, though the sluggish insidious mode of onset is much more common. On the other hand, acute febrile exacerbations may develop in some of the sluggish cases following an operation, the birth of a child, an attack of grip, or some other intercurrent illness. Holbrook¹¹ points out that this type of case often yields dramatically to the removal of a focus of infection, and I concur with him in this point of view. In a goodly number of these patients, however, the foci have already been removed during some previous attack, and it remains for the physician to treat the condition by other medical measures. In this connection, the existence of fever and actively inflamed joints is not a contraindication to the prompt removal of a focus of infection.

In my experience the active febrile type of case responds particularly well to foreign protein, or so-called fever therapy. I cannot agree with Holbrook that "shock" therapy, either by vaccine or by nonspecific therapy, is a hazardous procedure in patients with early or subacute forms of atrophic arthritis. This is just the type of case in which fever therapy is most valuable. I am aware, of course, that a good many physicians consider foreign protein by the intravenous route a radical and rather dangerous method of treatment, but in my hands I have seen no untoward results. For this work I use triple typhoid vaccine, which in its original strength contains 2,500 million organisms. A 1:10 dilution of this vaccine is made up, so that 1 cc. contains 250 million. The first injection consists usually of 50 million bacteria (0.4 cc.), and this dose is increased with each succeeding injection until a dosage of 500 or 600 million bacteria may be reached. If the dosage is not increased with each injection, the reactions become less and less marked. I usually give the patient from six to eight shocks during his stay in the hospital.

There are some, of course, who prefer to produce artificial fever by the "short wave" or by diathermy. I have produced hyperthermia by means of diathermy in a number of cases, usually with temporary benefit, but on the whole the results have not been so satisfactory as with typhoid vaccine, and certainly the latter method is much simpler to employ. In my experience typhoid vaccine injections actually give the patient less discomfort than the hot box.

The active febrile patients usually suffer considerable toxemia and rapidly become anemic and underweight.

They will need iron and arsenic in full doses. Following the suggestion of Haden,¹² I have given small doses of nearsphenamine to these patients with very good results.

Six or seven intravenous injections of typhoid vaccine will often reduce the patient's temperature to normal and the joints will show surprising improvement. At this stage the patient may be allowed to go home and treatment can be followed either at home or by visits to the office or clinic. Occasionally actual cure will result from this regimen, but more often the patient continues to have mild symptoms in the joints and falls into the category of a group 1 case. The treatment will then become that which has already been described under the group 1 heading.

GROUP 3.—Well Established Chronic Cases (from two to five years' duration).—This type of case is not incurable but presents much more of a problem than the two just described. The joints will usually have suffered more extensive injury than in the first two types. The cartilage may have been partially destroyed and the synovial membrane may have become thickened. Many of these patients present a typical villous arthritis in one or both knees.

This type of case needs institutional and orthopedic care. Unfortunately, institutions for handling such cases do not exist; that is, no sanatorium has been built as yet in this country for the exclusive study and treatment of rheumatoid arthritis. There is no more pressing need in America today than for institutions that will take care of arthritic patients. Given such institutions, in charge of men who are devoting their lives to the study and treatment of the disease, many of these patients with well established rheumatoid arthritis could be eventually rehabilitated and restored to active participation in life. Ober¹³ has a plan for the institutional management of arthritis in large communities. This is worth a careful study by those who are interested in the institutional treatment of chronic arthritis.

It is difficult to handle these well established chronic cases in the office or outpatient clinic. One always feels that whatever is gained by the treatment and by contact with the physician is offset by the discomforts of making the trip. This of course is not always the case. I have seen a few rather advanced cases of rheumatoid arthritis successfully handled in the office or outpatient department by a therapeutic regimen such as that outlined for the early mild cases. As a rule, however, they make some improvement at first and then become stationary.

In this type of case the medical man will need the almost constant help and cooperation of the orthopedic surgeon. Even with present institutional facilities, many of these cases yield surprisingly well to skilful treatment.

GROUP 4.—Advanced Bedridden Cases (of five years or more duration).—This type is represented by those unfortunate patients with rheumatoid arthritis in its terminal phase, in which treatment has availed nothing and the patient has gone on to the final stage of ankylosis and deformity. It is needless to say that little if any help can be extended to these patients by medical measures. Some of them are examples of neglect on the part either of the physician or of the patient himself.

12. Haden, R. L.: The Treatment of Chronic Atrophic (Rheumatoid) Arthritis, *Tr. Am. Clin. & Climatol. A.* 49:1 (May 9-10) 1933.

13. Ober, F. R.: A Plan for the Management of Arthritis in Large Communities, *New England J. Med.* 206:392 (Feb. 25) 1932.

There is also the type of patient who was born with a marked hereditary predisposition to the disease, and on him all forms of therapy may fail. Thanks to modern methods of treatment, fewer and fewer patients in this unfortunate group are seen. The therapeutic problem in this fourth type of case resolves itself into one of making the patient as comfortable as possible under the circumstances. Some relief can, of course, be achieved by the application of heat and massage. Such a patient demands a strong, capable and sympathetic nurse. Because of ankyloses, movement is extremely difficult and a change of position is necessary from time to time to relieve the strain and discomfort that result from lying too long in one posture.

COMMENT

In this presentation I have tried to summarize briefly my own point of view on the treatment of chronic arthritis, a point of view that is based on a fairly wide experience with the disease. This is, however, only one man's opinion, and the treatment of arthritis is still far from being standardized. I am sure it is no reflection on the men who are working on the arthritis problem to say that their opinion on the etiology and treatment of the disease changes from time to time and will continue to change until the nature of the malady is much better understood than it is at present. As I have already indicated, many physicians believe that rheumatoid arthritis is a chronic infection. My own belief is that it is a chronic streptococcal infection. But just what the underlying factors are that lead to its development, and just what factors determine recovery or progressive decline into the ankylosed state, no one pretends to know. However, much has been learned from investigation and from experience, and one can look forward with confidence to more and more light being shed on the problem during the coming years.

SUMMARY

1. The treatment of chronic arthritis differs materially for the different types of the disease.
2. Hypertrophic arthritis, being a degenerative process, is best relieved by the elimination of all trauma to the affected joints and by the application of such measures as will stimulate the local circulation.
3. Rheumatoid arthritis appears to be a chronic infection and should be treated as such.
4. Unfortunately there is no standard therapy for rheumatoid arthritis at the present time, but there are certain measures, such as rest, elimination of focal infections, physical therapy and regulation of diet, that have wide acceptance. Climatic therapy and vaccine therapy are also well thought of in many clinics.
5. My method of treating rheumatoid arthritis can be summed up in one word, "rehabilitation." This begins with rest and elimination of all foci of infection. Patients that show evidence of streptococcal infection receive streptococcus vaccine, usually by the intravenous method. In addition to these measures, a carefully regulated diet, reinforced by vitamins, adequate climination through the intestine, bladder and skin, and carefully supervised physical therapy are looked on as valuable adjuncts in the treatment. Iron and arsenic are the most valuable drugs for building up the patient, and salicylates are in high favor for relieving pain and discomfort.

33 East Sixty-First Street.

THE ORTHOPEDIC AND PHYSICAL
THERAPEUTIC TREATMENT OF
CHRONIC ARTHRITIS

LORING T. SWAIM, M.D.

BOSTON

The orthopedic treatment of chronic arthritis should start at the very beginning of the arthritis and should be carried along in close cooperation with the medical care.

There are three objectives in the treatment of chronic arthritis: (1) to control and stop the disease, (2) to prevent deformity during the course of the disease, and (3) to restore the patient to his normal life as functionally capable as possible. A fourth objective might be added to prevent recurrence of the disease. This might seem unnecessary but is an important factor in the follow up of every case. I consider this as important as any part of the treatment, since relapses are common.

The medical problem in the first of these objectives demanded of treatment I shall not discuss, yet there is a very practical way in which the orthopedist can materially aid in the success of the medical treatment. He can secure the best use of the body through training, just as is done in the development of every athlete; and the body resistance and strength come only with physical and functional perfection. This means good posture. Like every machine, to do its best work the body must be used correctly. The physiologic function must be as near normal as possible, especially in the chronic arthritic patient, who seems so totally unable to cope with his disease.

Faulty posture, or poor body mechanics, due to whatever cause—fatigue, carelessness, disease—does handicap the body in its work. A crumpled posture with sagged ribs causes pressure and displacement of the thoracic and abdominal organs. Their capacity to do normal work is inevitably decreased. Secretions and muscular activities are changed or inhibited entirely. Even under ideal conditions of rest, diet and hygiene this unnecessary hindrance to normal physiologic activity may prevent recovery, resistance may never be developed, and the many unknown factors may never be overcome unless the resistance of health can be secured. Such health comes only from the inside, depending on whether normal physiologic function can be restored.

OBJECTIVES OF TREATMENT

All arthritis is a constitutional disease. Inflamed joints are only a symptom of it. It seems evident that the fundamental physiology of the patient with rheumatoid arthritis is not normal. The heat regulating apparatus is disturbed. The circulation is out of order, as manifested by variations in the superficial circulation of the skin and extremities, especially the fingers and toes. These variations are undoubtedly present in other parts of the body, especially the organs of the abdomen, which are not accessible to observation. The vasomotor control is unstable. The basal metabolic rate is very often subnormal. The blood pressure is low. The function of the gastro-intestinal tract is below par. There is always secondary anemia. This evidence points toward a disturbed physiologic and

subnormal functioning of many parts of the body. Much of this disturbed physiologic functioning can be ascribed to incorrect use of the body and faulty posture, which crowds the abdominal viscera. It is not at all infrequent to find that correction of posture by systematic corrective exercises and rest, with corrective positions, remedies many of the functional physiologic failures that I have mentioned. Therefore, from the very beginning of the treatment of arthritis the orthopedic surgeon, by correction of posture, can very materially aid the medical man in his fight to stop the disease. The correction of posture can be best started by rest positions in bed, where the treatment of every case of arthritis should begin. Regular positions of hyperextension, with the pillow under the shoulders, with the hands under the head, will expand the chest, widen the costal angle and raise the diaphragm. This raises all the organs of the abdomen, and the normal pump action of the diaphragm gives better circulation throughout all parts of the abdomen and extremities. A three weeks trial of this position for one-half hour three times a day is adequate to convince one of the truth of this statement.

Another position of circulatory importance is the face prone position, which is simply lying face down over a pillow. It changes radically the position of all the abdominal organs and thus relieves pressure and pull when the patient is on his back in bed. Combined with this corrective work, physical therapy is of immense importance in the stimulation of circulation of the joints by the use of general body exercise. This consists of breathing, abdominal exercise, rib stretching and the use of the trunk. General massage also stimulates circulation in the extremities, but one must be careful about touching joints that are inflamed.

While the patient is in bed, heat can be used with great benefit. It promotes better body temperature. Hot air bakes, steam baths and hot packs to the abdomen and back are often used. Local circulation is improved by packs, bakings, diathermy, infra-red radiation and sunlamps. These relieve pain and promote rest, relaxation and circulation. Fatigue must be avoided. Later good use of the body can be maintained during the convalescence while the patient is unable to stand or sit correctly, by the temporary use of supports. These are corsets, braces or even jackets. It is not necessary to go into details here. This can be found in the literature. Suffice it to say here that correction of body mechanics is being found of increasing value in the treatment of arthritis as developing a background for the restoration of normal physiologic function and functional stability, on which normal chemistry and resistance to the disease and environment depend.

Resistance to environment seems to be completely lost in most arthritic patients of the rheumatoid type. Restoration of the physiologic function as well as control of the environment seems increasingly necessary for recovery.

The second way in which the orthopedic surgeon is able materially to help the arthritic patient is through prevention of deformity early in the disease. It seems as necessary to prevent deformity as to control the disease itself, because in the past it has been found that many patients who have been cured of arthritis have been unable to lead a normal life because of the deformities that have resulted. The keynote of prevention of deformity then is to anticipate what is likely to happen and to see to it that flexion, which is the characteristic deformity of all rheumatoid arthritis,

does not occur. Almost every deformity in arthritis is a flexion deformity. Flexion is due to contraction of muscles. Contraction of muscles is the result of an attempt to stabilize or splint the joint during the acute, painful stage. If nature's attempt at splinting is anticipated and the joint is put at rest in light plaster splints before the muscles have been brought into play to protect it, the necessity for muscle spasm is avoided. The patient relaxes the protected joint with comfort. Rest is secured with the relief from strain and irritation. The artificial protection is given the joint before the muscles have had a chance to produce flexion deformity. It has been found that the disease itself subsides much more quickly, the patient has more comfort, requiring less analgesic medicine, and the acute stage of the disease is materially shortened. Early protection is necessary, however, to accomplish this end. Thus much time is saved, the patients are relieved of the necessity for splinting the joints themselves, and the joint deformity is far less likely to occur.

There are, however, certain dangers that must be recognized: Rheumatoid arthritis tends toward ankylosis. In order to avoid this danger the supporting plasters must never be left on a joint more than forty-eight hours. Usually by this time the joint inflammation has subsided sufficiently to allow gentle motion. The plaster is bivalved and the joint is moved a little each day, so that the danger of adhesions is overcome. The irritation of these daily exercises is minimal, as during the greater part of the time the joint is at rest. Gradually the time of exercise is lengthened while the time of rest is shortened, until finally the joint needs protection only at night. Protection at night is more important than during the day because if people are observed when they are asleep it is found that the joints are invariably flexed at this time. After the disease is quiescent the use of the joint is permitted during the day. It has been my experience that in this way not only are deformities prevented by being anticipated, and protection given in time, but more motion is secured in the joint as a result of this early rest.

It seems probable that much of the inflammation in the joint during the acute stage is aggravated by the trauma of use, and much damage is produced. In support of this theory it was found that the right hand of a right-handed person was invariably worse than the left, and vice versa. Use, therefore, during the acute stage injures the joints. Since I have been using splints and protection I have had better functional results in the final outcome than when the joint was not protected. It is a very simple thing to make plaster splints. It can be done in the hospital or at home with slight expense or trouble. The splints can be renewed whenever necessary. They are comfortable, easily adjusted and usually fool proof, but they should not be left on too long. One must constantly have in mind the possible deformities that will occur in joints, and with the first indication of inflammation in a joint, the doctor in charge should be on the lookout for trouble and forestall it. In making splints for the joints, position is important. If ankylosis is going to take place, the most usable position should be thought of and also the one of greatest relaxation for the joint in which all muscle spasm is relieved. This simply requires a little thought and imagination.

The third object in orthopedic treatment of chronic arthritis is correction of deformity and the restoration of joints to normal function as far as possible. This

may first be attempted by the same method I have described for prevention. A joint that has already begun to flex but is not too bad very often will straighten out if the plaster splint is applied, and without strain the joint is held in a rested relaxed position for a day or two. It will be found at the end of this time that the muscles have relaxed so that the joint can be straightened several degrees farther. A new plaster is then applied in the new, corrected position. Again the joint is rested. This may be repeated indefinitely as long as correction is being obtained. The plaster, however, must be bivalved and the joint allowed exercise as in the case of early prevention. In this way in all parts of the body many cases of contracted joint deformity can be corrected. It requires meticulous care and constant supervision.

The second method of correction of deformity is by corrective splints such as the Thomas caliper splint for the knees, various banjo splints for the hands, cock-up splints for the wrists and the airplane splint for the shoulder. The third method, in cases in which correction cannot be obtained by those already mentioned, is manipulation of the joints under an anesthetic. Breaking up of adhesions is often of great value. One must, however, carefully select the case and be absolutely sure that the arthritis itself is in the quiescent stage, because manipulation of an active joint often results in complete ankylosis and increases this tendency to fusion. Manipulation should also be very carefully done, because there is danger of breaking the bones when the bones are much atrophied. It is not at all uncommon to obtain a traumatic fracture of the lower end of the femur as a result of manipulation of the knee, and fracture of the radius is not uncommon in manipulation of the wrist.

The fourth method of correction of deformity is by open operation. Operation on arthritic joints is not the serious matter it once was considered. Apparently arthritic joints heal easily and are no more apt to become infected than any other kind of joints, and the operation on an arthritic patient carries no more risk than on other depleted persons. It is, however, absolutely essential that in operating on an arthritic joint the disease itself should be as near a quiescent state as possible. It is, of course, sometimes necessary to operate before the quiescent stage is complete in order to prevent catastrophe, but as a rule one should wait until the disease is quiescent.

Time does not permit me to go into the technic or description of all the various operations. These can be obtained from the several articles on this subject. There are, however, a few operations that have been satisfactory in the hands of men who are accustomed to operating on arthritic patients. One of the most successful of these is the posterior capsuloplasty developed by Dr. Philip D. Wilson. When the posterior capsule is tight and contracted and has become very much thickened, manipulation is not successful. Correction is impossible without splitting the posterior capsule and stripping the lower end of the femur in back. This operation is most successful in correction of the flexed position of a knee when there is only a little subluxation and the patella is free. Synovectomies are of value in joints blocked by synovial overgrowth. Arthroplasties have been performed on the knee quite successfully in many cases. Arthroplasties on the elbows are almost invariably successful, giving a very

satisfactory, useful arm. Operations on the hands so far have not been entirely satisfactory, although progress is being made in developing different forms of technic for such operations. Occasionally operations on the hips are useful, but they are apt to leave a rather unstable joint. They are, however, used in many cases to give a movable joint. Osteotomies can be used to correct adducted legs when the hip is stiff. One of the most important things to remember in the operative work on arthritic joints is that the patient should have a period of intensive training before the operation is performed. We have found at the Robert Breck Brigham Hospital that a month or two of training of the affected leg or arm in muscle exercise and control is important because motion can be begun sooner after operation as a result of such training. The patient is prepared to do the various exercises required as soon as the wound is healed, and far better results have been obtained in operative cases by this preoperative training.

Here logically is the place for physical therapy. The principles back of physical therapy in arthritis are age old. They are directed toward improvement in local and general circulation, relaxation, and the development of muscles. Good circulation produces healing, and heat in any form, dry, moist or diathermy, improves circulation, drawing blood to the part. It is the first physical agent to be thought of in arthritis. The general principle of all heat is to dilate the superficial blood vessels, to bring circulation to the inflamed joint and in this way promote healing and relieve pain, congestion and swelling. Heat has also been used in a general way in order to promote sweating and general relaxation and to raise the temperature to produce fever. Many methods have been used for this, such as the big dry baker, the mud bath and the steam bath, and, recently, diathermy to raise the temperature of the body has been tried with reported success.

The second physical agent used is massage. This stimulates the circulation in the skin and muscles and secures a fresh blood supply to unused muscles. It acts as a passive exercise and has been found to be very beneficial in the treatment of arthritis. However, the massage of swollen joints is not indicated, is apt to produce trouble and should never be done. General massage promotes better general physiologic function and better muscle tone and is very beneficial for those who, being bedridden, are unable to take any form of exercise.

Exercise is the third physical agent. As soon as a person is able to do exercises himself, active exercise is the best way to secure muscle massage and heat regulation. In exercising one should always consider the use of the joint, for overuse is detrimental to it. Exercises should be directed toward body correction first. Such corrective posture exercises as deep breathing, abdominal muscle control, rib stretching and use of the diaphragm and trunk are ideal and are permissible even in bed with patients who are unable to use their joints. Regular, systematic training in breathing and use of the diaphragm have permanent beneficial effects on the circulation and functions of the body. They have often been found of great benefit at the early stage of the disease in keeping up the tone, circulation and physiologic function of the body. Fatigue should be avoided in all cases of arthritis. Exercises should never be pushed to the point of fatigue.

I have said very little about hypertrophic arthritis, or osteo-arthritis, because it has much less serious consequence than the rheumatoid disease. It is a degenerative disease of increasing years and is the result of gradual injury of the joints. It is a reaction to trauma. When the trauma stops the changes stop, and the principle of orthopedic treatment is the rebalancing of the weight to stop the strain on the feet, knees, hips and back. Correction of the mechanical use of the body and a support for the joints involved, such as plates, knee splints, back braces, corsets and Thomas collars, which relieve the mechanical strain, are called for. The details of orthopedic treatment can be best found in orthopedic textbooks.

CONCLUSION

Arthritis is a constitutional disease. It requires all the care that can be given to control it, as it involves the joints, and deformity is a result of the disease. Orthopedic consultation should be obtained at the beginning of the disease before deformity has occurred. The attempt to correct the deformity is quite unsatisfactory, and prevention is comparatively easy in the early stages. This is secured by the use of light splints in anticipation of what is likely to happen; protecting joints during the acute stage is the quickest way to relieve pain in them. Splints should never be continued for long periods. Rest shortens the convalescence. Joints that have been deformed can be corrected in many cases by the use of supports applied serially, by various forms of apparatus that cause forced stretching, by manipulation and by surgery. However, joints are never so good after deformity has once occurred, no matter what method of correction is used, as if the deformity had never been allowed to take place. To this end the challenge to the orthopedic surgeon is to work in conjunction with the medical man from the very beginning of the arthritis and never to relax his efforts to promote normal physiologic function by correction of postural defects and to keep the joints from developing contraction deformities.

372 Marlborough Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRs. IRONS, CECIL AND SWAIM

DR. WALTER BAUER, Boston: An accurate diagnosis is the first requisite in treating any patient with joint disease. Accurate diagnosis and classification of joint disease are much easier if one employs a simple classification such as that proposed by Allison and Ghormley, who divide joint disease into two groups: (1) etiology known and (2) etiology unknown. The arthritides discussed here fall into the unknown group. One must appreciate that these two forms, degenerative and rheumatoid arthritis, are in no way causally related even though one individual may have both diseases. Degenerative (hypertrophic) arthritis is not caused by a bacterial agent. It represents a form of joint disease in which the joint changes are degenerative in nature, resulting from the "wear and tear" of life and increasing age. Such joint changes may be present and yet cause no symptoms. Treatment is often not indicated; if so, weight reduction and the correction of faulty body mechanics are most important. One must remember that no treatment can be expected to restore the joint to normal. It can only relieve an already diseased joint. After listening to these papers, one appreciates that no standardized treatment for rheumatoid arthritis exists. There are a number of reasons for such a state of affairs: 1. It is a disease of unknown etiology. 2. The natural course of the disease without treatment is not known. 3. The disease is characterized by remissions and relapses. Remissions may last months or years. Therapy has often been given credit for such remissions, and

in consequence all manners and forms of treatment for the arthritic patient exist. 4. Each arthritic patient is an individual problem and therefore should not be subjected to a standardized form of treatment. No one has a right to speak of therapeutic results unless the conditions of study are very rigidly and adequately controlled. There is no specific treatment. Rest, both mental and physical, is most important. However, maintenance of joint motion is essential. Physical therapy is most important. I cannot subscribe to all the claims made for posture. The diet should be well balanced, adequate in respect to vitamins, calories, calcium, phosphorus and iron. There is no proof that a low carbohydrate diet is indicated or efficacious. Next in importance are removal of focal infections, orthopedic measures, foreign protein therapy, hyperpyrexia, climate, psychotherapy, drugs and vaccines. Vaccine therapy allows for frequent visits, thereby enabling one to observe the course of the disease and suggest many helpful measures.

DR. LINN J. BOYD, New York: The chronic nonspecific arthritides can be resolved into two components: first, the constitutional element; second, the releasing factors. The danger of the constitutional approach lies in an unjustified therapeutic resignation arising out of a misconception of "constitution." Paradoxically, although many syndromes now compose the heterogeneous conglomerate of chronic deforming arthropathies and though one may fully anticipate the removal of many under new names, it is possible that attention has been focused too intently on the joint manifestations. Careful study of several hundred case histories indicates clearly a prodromal stage of fleeting neuralgias, localized cyanosis, "dead fingers" and a wide range of symptomatology suggestive of the view that the joint picture is a late event in the evolution of the disease. To review the releasing factors here would be impossible and unprofitable. Although many groups of releasing factors are appreciated, they are frequently not considered in the single case: direct traumas by mechanical disturbances are continually overlooked as well as marked overweight and underweight; I have seen the combination of Perthes' disease and Köhler's disease only twice, both instances occurring in pituitary dwarfs; Beck's disease is apparently characterized by goiter and arthritis; probably other endocrine glands may play rôles, so that there is an endocrine panel in the constitution. The suggestions afforded by the joint lesions of gout, of ochronosis, are indicative of joint damage of metabolic origin. The joint phenomena of syringomyelia and tabes imply the possibility of neurotrophic phenomena in arthritis. The doctrine of focal infection was a great advance in the conception of the chronic nonspecific arthropathies and occasional cases may be encountered in which the removal of a focus is followed by prompt remission of symptoms. In my experience these cases are not common even in the so-called infectious group. I advise removal of foci with the expectation of preventing the development of some serious diseases but without much expectation of influencing the existing arthritis. In regard to vaccines, I have gradually found less and less occasion for their use, although at times they yield brilliant results. I use iodine almost as a routine procedure; I prefer ordinary tincture of iodine, giving drop doses well diluted in water, going from one to nine drops daily and then down. Several such courses are repeated.

DR. W. PAUL HOLBROOK, Tucson, Ariz.: A tremendous advance in the care of arthritic patients would occur if physicians would accept the broad constitutional, many-sided etiologic factors that Dr. Irons brought out in his paper. The disease is constitutional and must be approached not from one angle but from every possible deviation from the normal in the individual patient. There was one point in Dr. Cecil's paper that I thought warranted emphasis: the question of vaccine. It should be remembered that vaccine or any other so-called specific therapy, if it is recommended as a specific therapy, is used by the general practitioner to the exclusion of the fundamental physiologic program. If that is not true, there should be no criticism of the use of vaccine by competent investigators. The hazard exists only in ignoring the more fundamental problems of the patient's disease. So far as Dr. Swaim's paper is concerned, I simply want to emphasize the importance

of his statement, because, of the last 1,000 patients that I have seen with atrophic arthritis, 85 per cent entered the clinic with a preventable deformity.

DR. MAURICE F. LAUTMAN, Hot Springs, Ark.: The greatest step forward in the conquest of arthritis was made when the fact was established that arthritis is not primarily a disease of the joints but rather a constitutional disease that eventually affects the joints. Dr. Irons' excellent dissertation leaves but little to be added. His insistence on a broad-viewed attack on the disease makes it clear that any successful plan of treatment must include the correction of every physiologic abnormality. I believe, however, that the simultaneous employment of every measure that offers any possibility of help for these patients is infinitely more effective than temporizing first with one plan of attack and then with another. One phase of the treatment of arthritis that deserves greater emphasis in this country is the spa treatment. This does not refer to this or that fanciful constituent of the water at any particular spa but rather to the regimen at the better type watering place or health resort. Most of them are situated inland and from a climatic standpoint are ideally suited to the arthritic patient. The communities that house them are usually small and free from industry, and the clear air and restful surroundings are a tonic in themselves. The change in environment with freedom from household cares and business worries permits a degree of mental rest that is so important and yet so difficult to obtain at home. Patients coming to a health resort usually do so because of some friend who has achieved a spectacular cure, and the idea of coming to a place where they are going to get well is an excellent mental stimulus for these habitually discouraged patients. Being imbued with the idea of getting well, they enter wholeheartedly into the business of getting well, cooperating much better and following instructions to the letter. The value of hydrotherapy and physical therapy has become increasingly evident in recent years. The beneficial effect of supervised exercise, hydrotherapy and physical therapy is always enhanced by the employment of adequate periods of rest, which the spa regimen affords, and any one who treats many cases of arthritis will agree that a regimen which includes the correct application of rest, exercise, diet, hydrotherapy and physical therapy will meet most of the requirements for the successful treatment of arthritis.

DR. S. C. WOLDENBERG, New York: Sulphur therapy in the treatment of arthritis was introduced at the veterans' hospital, Bronx, New York, in February 1932. Research in Europe had established its value and it was introduced as an adjunct to a comprehensive treatment called for by the individual needs of each patient. The results obtained exceeded our most sanguine hopes. There are more than 60,000 veterans disabled by arthritis. They show a disease history averaging over ten years, some with continuous hospitalization exceeding two or three years. Of 150 patients aged from 38 to 42 years, treated with sulphur, two thirds were advanced cases; six had every joint involved. Maximum hospitalization under the sulphur therapy was 129 days. All were cases of atrophic arthritis. The colloidal sulphur (sulphur diaspore) used was in two forms: 10 mg. for intravenous medication and 20 mg. for intramuscular medication. A high temperature, inflamed joints and marked perspiration followed the intravenous injections in many acute cases. After the fifth or sixth injection the spasticity of the muscles, the effusion in the joints and the pain began gradually to disappear. We made one radical departure. Whereas 5 mg. of sulphur twice or three times a week had been the maximum known, we found it necessary to give as much as 10 mg. every day in severe cases to obtain beneficial results. The cystine in this group ranged from 6.5 to 9.8 per cent prior to treatment. Sulphur was given until a normal of from 12.5 to 13.5 per cent resulted. The sedimentation rate was inversely proportionate to the percentage of cystine. Treatments, it was found, decreased the leukocyte count when a high count was observed. I believe that it must be considered a possibility that infection, metabolic deficiency and circulatory disorders—not one, but all—are factors, although any one of them might be responsible for the break in compensation that brings on the onset of arthritis. Each case

requires individual study. Sulphur therapy, despite its great value in our opinion, can be recommended only as an adjunct. That the sulphur deficiency in patients with arthritis can be remedied is confirmed by our experience. Treatment was found effective in freeing the patient from pain, removing acute symptoms and improving metabolic stability. Although clinically each case showed decided improvement, no joint changes demonstrable in a roentgenogram were apparent as a result of treatment. The results obtained warrant further study under auspices appropriately suited to this purpose.

DR. HEINRICH F. WOLF, New York: Dr. Irons succeeded admirably in stating the problem and indicating a promising approach. But when he speaks of a workable classification, the question arises just what that means. When one speaks of therapy, a classification on pathologic anatomic grounds is of no value except for prognostication. Grouping may become a dangerous procedure as, in giving treatments, one is always dealing with an individual case and not with a group. This is evident in the use of physical therapy procedures. Rheumatoid arthritis is considered of infectious origin. Suppose the foci have been removed. There still remains a rheumatoid arthritis. But while therapeutic procedures, such as heat, may have been wholly unsuccessful before the removal of the foci or may even have aggravated the condition, they may be very helpful after the removal of the foci. That means that the identical pathologic condition in the same patient reacts as two entirely different disease entities. Or let osteo-arthritis be considered. It makes all the difference whether this condition is due only to wear and tear or whether it is complicated by an infectious process. In the latter case, according to present views, there exists an osteo-arthritis combined with a rheumatoid arthritis and the classifications are topsy-turvy. I advocate a management of the acute arthritis which differs radically from that suggested by Dr. Swaim. Is rest, as he recommends, a treatment? I have pointed out in my textbook on physical therapy that the ideal treatment of acute joint conditions is the application of iced compresses. They reduce the inflammatory process, the edema, the arterial hyperemia that is harmful because of the disturbed lymph circulation. They relieve the pain immediately and greatly shorten the course of the disease. I don't know of failures. The physiologic basis for this treatment has been established by Landis, Drury and Jones, Goldsmith and Light. Their experiments explain the disastrous effect of heat applications. I advocate even massage after the very acute symptoms have subsided and no pus is present. Under massage, I understand very gentle effleurage. It instantly relieves the spasm and the pain. The remarkable relief of pain by the use of iced compresses and gentle massage permits early motion and thus aids restoration of function.

DR. WILLIAM J. KERR, San Francisco: These papers bring together the soundest information available on the subject of chronic arthritis, with especial reference to the atrophic arthritis. A good many discussions in the arthritis committee have been held during the last two or three years about bacteria, positive blood cultures and specific vaccines in chronic arthritis, and it seems to me that an opportunity has been lost to make some controlled studies. If physicians were as careful in making blood cultures of other patients who have debilitating diseases as they are in atrophic arthritis, about as many positive cultures in the blood as in that disease would be found. The profession may be going through the same experience it did many years ago in Hodgkin's disease. It has seemed to me that there are a number of methods of treatment that have a common denominator, and perhaps this should be kept more in mind when considering every new method of treatment introduced. I believe that in most every valuable method of treatment there is improvement in the circulation of the joint by local treatment at the site, or improvement in the circulation of the joint or joints through improved general circulation. I wish only to mention some of the methods by which this may be brought about. Among the general measures may be suggested climatic change. If this is considered in the proper light, I think it will be agreed that a warm climate will perhaps open the periphery a little more, and perhaps the contrasts between day and night that are experienced in the southwestern

desert regions will help to reeducate the vessels to the joints to promote better local circulation. The various methods of producing nonspecific protein shock, or the use of drugs by which a reaction is brought about, will tend to open up the periphery and improve the circulation of the joints. Perhaps many of the so-called specific vaccines react in this manner. Possibly there is a streptococcus toxin that may act like tuberculin and may have to be considered differently. Possibly vitamin C, which has a very important action on the cement substance of vessels, will be found to be beneficial. The use of sympathectomy or other measures affecting the vasomotor nerves leads to an improvement in the circulation to the joints affected. There are, of course, the various local measures of treatment, which bring about hyperemia, either passively, such as hydrotherapy, warm baths and mud baths, which tend to bring about temporary improvement in circulation, and then the use of cold packs or ice, which bring about a reactive hyperemia. The use of liniments, counterirritants, blisters and so on act by producing hyperemia locally. Then there are massage and a variety of other measures.

DR. H. M. DAVISON, Atlanta, Ga.: The last eighteen months Dr. Mason Lowance and I have been using a cabinet type of fever producer called a hyperpyrexator. This machine produces the heat by the use of the infra-red burner. The advantage is that the fever production is not caused by the introduction of any foreign substance. The temperature produced may be controlled, and the patient suffers relatively little discomfort. The treatment is safe and may be given in the doctor's office. A large percentage of the cases have been sent to us and treated in conjunction with the orthopedic surgeon or other internists. They had already been treated by different methods for periods varying from six months to fifteen years. The temperature of these patients has seldom been raised above 103.5 F. The number of treatments varied from three to thirty. We have treated 120 cases. Approximately 33 per cent of the patients have had total relief from pain and varying degrees of therapeutic functional improvement. These cases varied from one rather marked deformity to lesser degrees. The varying amount of therapeutic functional improvement in some cases has been marked. In others it has been slight, depending somewhat on the type of deformity. In addition to this 33 per cent of total relief, 40 per cent have received marked improvement. Only 3 per cent have not been improved at all, and only 8 per cent have received so little improvement that the patients themselves did not count the treatment worth while. We believe that this method of producing therapeutic fever will prove to be a valuable adjunct in the treatment of chronic arthritis.

DR. S. ADOLPHUS KNOFF, New York: Being interested mainly in tuberculosis and hardly ever seeing any cases of arthritis, I have but little to add. There is, however, one physical therapeutic means which I employ for tuberculous patients with apical lesions, which I think should also be helpful in the management of arthritic cases. I refer to diaphragmatic respiration, which, I think, justly deserves to be classified as a physical therapeutic means. When one deals with an intelligent patient, this method of breathing is not difficult to teach, but with the less intelligent it often requires a good deal of patience and time. I have described the method in my official report to the United States government on tuberculosis and in a number of other contributions. I shall be glad to send a detailed description of how to teach this method to any one who asks for it. What benefit could an arthritic patient derive from abdominal breathing? Aside from the many reports I have received from physicians who practice this method on patients or on themselves, I shall quote only the following: "It helps to relax, it quiets the heart, it lessens fatigue and increases endurance. It improves the portal circulation and thus prevents the distressing symptoms of gas accumulation in the abdomen." The method has also a distinct psychologic effect. The patient cannot practice diaphragmatic respiration without concentrating on it. In other words, he cannot think of anything else except his slow inhalations with the aid of the diaphragm and the equally slow exhalations. He forgets about his physical suffering and is even helped to fall asleep.

DR. JAMES PATTERSON, Scarsdale, N. Y.: In observing many clinics handling arthritis, I find that each one is inclined to ride a hobby, whether it is the use of serum, vaccine, postural rest or what not. The thing that is common to all of them is giving the patient rest, good physiologic hygiene, and encouragement. Dr. Irons said that the duration of this disease is fourteen years. That is quite conservative. How many practicing physicians can keep a patient who is continually uncomfortable, continually crippled, under observation and keep him encouraged for a period of two or three years? Few can. Dr. Cecil says that the patient must reduce his weight. That is good, but one must study the patient before one has him reduce too much. The loss of 25 pounds (11 Kg.) may give quite as much distress to the gastro-intestinal tract of some patients as it will give relief to others from the reduction of pressure on sore joints. In these cases a great many remissions and exacerbations occur, and sometimes the disease is self limiting. After the pain is gone, the patient still has the mental lameness and the inability to use the muscles, which has been engendered by the long continued distress, and one has to start muscle reeducation. If one does that, an astonishing increase in movement occurs. The things to keep in mind are that it is practically impossible to keep a patient with this very chronic disease under one's own hands long enough for practical benefit; physicians should arrange through the committee on arthritis for special hospitals for such cases and send them there as soon as the diagnosis is made, because prolonged rest is more needed than anything else.

DR. A. S. GORDON, Brooklyn: I would like to subscribe to the view expressed here that the so-called rheumatoid arthritis is of infectious origin and that the etiologic agent in the vast majority of cases is in all probability some form of streptococcus. Dr. Cecil has succeeded in isolating in most cases a hemolytic streptococcus. This is not my experience. I found in most cases a nonhemolytic streptococcus. It is almost an axiom in medicine that every one has or has had some form of tuberculosis and that all, or almost all, have become immunized to it. Those who have not succeeded in developing that immunity passed on long ago. Of those who remain, a certain number will develop sooner or later some active form of tuberculosis, usually some chronic form. By similar reasoning and analogy, almost all have, or have had, some form of streptococcal disease, and almost all have become immunized to it. A certain number will break down sooner or later in life with some form of chronic streptococcal disease, and I believe that chronic streptococcal disease is a definite clinical entity. Analogous to the tuberculin type of reaction, in most adults there is a common type of an intradermal reaction due to some primary streptococcal disease similar to the tuberculin test. For a few years I have been working on a large series of cases, which have included anywhere from the very first attack of arthritis following acute infection up to the type of case lasting for thirty-one years, and I have been working with toxins instead of vaccines, as Dr. Cecil has. I found in treatment that a modified toxin or a detoxified toxin was very encouraging in its results, and I have continued this treatment for quite a long time. Some patients have been under observation for as long as two years, and some of them have been discharged more than a year and they are still doing fairly well. The diet is just as important as it is in tuberculosis. The general mixed diet is important in any chronic type of infectious disease. As to the question of allergy in this infectious type of chronic arthritis, I believe there are two factors that stand out showing the importance of allergy in this disease. First, the joint manifestations in the real type of infectious arthritis usually occur one, two, three or four weeks following an acute infection, such as an acute tonsillitis. Homer Swift in his work on acute rheumatic fever refers to this fact as the secondary infection, calling the first disease the primary infection and the joint manifestations the secondary infection. The other fact that I consider very important is that the rheumatoid arthritis joint never suppurates. I think that these two facts, that it follows an acute infection and that the joint never suppurates, account for the allergic state of this disease.

NEW ORLEANS

Following the contributions of Aran,¹ Charcot,² Marie and others the essential pathologic lesions responsible for the various myopathies have been diligently studied. Still these attempts have resulted in few fruitful rewards. At present, with the usual standards of diagnosis, accurate determination of the etiologic factors in most of these cases taxes the diagnostic acumen of the best trained clinicians. It seems desirable, therefore, to study the various myopathies, from a metabolic as well as from a clinical point of view, with the aim of evolving observations that may have diagnostic and prognostic applications as well as distinct therapeutic value.

The advent of amino acid therapy in the treatment of myasthenia gravis, primary muscular dystrophy and secondary muscular atrophy has opened such vast and comparatively fertile fields of scientific endeavor that it appears that the biochemical investigation of these cases should result in many interesting and important contributions, particularly as to unbalanced creatine-creatinine metabolism, morbid physiologic processes, differential diagnosis and prognosis, and so has it been.

This newer concept has already resulted in distinct important contributions, especially as regards the clinical therapeutic results in cases of myasthenia gravis and pseudohypertrophic muscular dystrophy. However, differences of opinion have arisen concerning the various metabolic relationships and therapeutic effects following amino acid therapy. Especially is this so in certain types of muscular dystrophy and that large group of cases usually referred to as muscular atrophy secondary to pathologic lesions in the central nervous system, or abolition of function of the lower motor neurons—the so-called second trophic units.

In view of these conflicts, metabolic studies were made on thirty-four patients, representing eleven distinct types of myopathies and atrophies, grouped according to their clinical diagnosis. The creatine-creatinine metabolism of each patient was studied for a period of five days before the amino acids were administered. It was also studied through three similar periods of five days each after the therapy was begun. The metabolic determinations were reviewed in the light of the diagnosis and subsequent clinical results in each case in an attempt to elucidate correlative information.

For convenience, we have classified the cases more or less on a pathologic-clinical basis, as recommended by Wechsler,³ rather than as eponymic entities (table 1).

CREATINE-CREATININE METABOLISM

Women and children may eliminate a certain amount of creatine which is considered physiologic, but creatine is usually not excreted in the urine of normal adult men. The creatinuria observed in any condition is somewhat dependent on the protein intake. There was no attempt to make studies of nitrogen balance in our work because the nitrogen balance is not of particular importance as regards clinical results, as long as the patients obtain sufficient protein for normal metabolism. Creatinuria has also been observed by numerous investigators in many diseases affecting the muscular system, a review of which up to 1928 may be found in Hunter's monograph.⁴ It was also present in the following instances: in cases of progressive muscular dystrophy, reported by Milhorat, Techner and Thomas,⁵ Milhorat,⁶ Kostakow and Slauck,⁷ Harris and Brand,⁸ Tripoli and Beard,⁹ Reinhold, Clark, Kinsley, Custer

TABLE 1—Classification of Syndromes of Muscular Dystrophy, Muscular Atrophy, Myasthenia Gravis, and Strabismus

Group I—Primary Myopathies
1 Primary muscular dystrophy (usually of the lower limbs)
(a) Progressive muscular dystrophy
(b) Pseudohypertrophic (Duchenne)
(c) Facio-scapulo-humeral (Landouzy Dejerine)
(d) Bulbar (Hoffmann)
(e) Juvenile scapular (Erb Zimmerlin)
(f) Infantile hereditary (Leyden)
2 Amyotonia congenita (Oppenheim)
3 Myotonia congenita (Thomsen)
(a) Early life (hereditary)
(b) Myotonia acquisita
4 Myotonia atrophica
5 Muscle wasting from disease
Group II—Progressive Nuclear Muscular Atrophy
1 Mainly of small muscles of the hand (Aran Duchenne)
2 Hereditary, familial, of infancy and childhood (Werdnig Hoffmann)
3 Subacute and chronic poliomyelitis
4 Bulbo-facial of childhood (Fazio Londe)
5 Progressive bulbar palsy (glossolabiolaryngeal, of Bouchard)
6 Chronic progressive ophthalmoplegia (von Graefe)
7 Multiple sclerosis
8 Amyotrophic lateral sclerosis (Dejerine)
9 Progressive spinomuscular atrophy
10 Friedreich's ataxia
11 Paralysis from Jamaica ginger poisoning
12 Paralysis from peripheral nerve injury
13 Paresis with muscle atrophy
Group III—Myasthenia Gravis
Group IV—Strabismus

and Connell¹⁰ and Mettel and Slocum,¹¹ in cases of progressive pseudohypertrophic muscular dystrophy, reported by Brand, Harris, Sandberg and Ringer,¹² Milhorat, Techner and Thomas,⁵ Chanutin, Butt and Royster,¹³ and Tripoli and Beard;⁹ in cases of amyotrophic lateral sclerosis, reported by Milhorat, Techner

would increase the creatine content of young rat muscle, Milhorat, Techner and Thomas⁵ fed glycine to patients suffering from muscular dystrophies and were the first to observe its definite therapeutic effects. These important results have stimulated many clinicians to use glycine, with and without ephedrine, in the treatment of various types of myopathies. Cases of myasthenia gravis¹⁹ and pseudohypertrophic muscular dystrophy²⁰ have shown the most remarkable recovery. However, while some of the muscular dystrophies have been greatly benefited, no objective improvement has been observed in a few far advanced cases of this type and in the neuromuscular atrophies. In several of the two latter conditions, however, the progress of the disease was apparently arrested and only subjective improvement was noted as long as glycine therapy was continued. We have reviewed the literature on the clinical results and metabolic studies of amino acid therapy in several different types of myopathies elsewhere.⁹

of Folin.²² The daily excretion of total creatinine minus the excretion of the preformed creatinine multiplied by 1.16 is equivalent to the daily creatine output.

RESULTS

The clinical and biochemical results obtained in thirty-four cases are listed in table 2. For purposes of comparison, the cases may be classified into three groups.

Group 1 (cases 1 to 10). Cases in which the average creatine excretion rose from 50 to 200 per cent above that of the control period, provided this increased creatinuria soon disappeared in the third or subsequent period, showed both subjective and objective improvement.

Group 2 (cases 11 to 17). Certain neuromuscular cases that presented about the same degree of increase or decrease in creatinuria as those of group 1 showed only subjective improvement or merely an arrest of their symptoms.

TABLE 3.—Cases in Which Amino Acid Therapy was Given in Which Metabolic Studies Were Not Made

Case	Age, Years	Amino Acid Daily, Gm.	Duration of Therapy, Months	Myopathy	Progress Report
35	21	Glycine 10-15	7	Myasthenia gravis	"Masklike" expression disappearing; clinical condition very much improved
36	32	Glycine 10-15	6	Myasthenia gravis with extra-ocular paresis	Definite improvement demonstrable, and loss of vertical diplopia with return to apparent normal after three months
37	6	Glycine 10-15	8	Pseudohypertrophic muscular dystrophy	Early case with practical return to normal physique and function
38	26	Glycine 10-15	11	Pseudohypertrophic muscular dystrophy	Walks without crutches or cane with ability to perform all normal movements; physique improved; characteristic posture remains
39	44	Glycine 10-15	16	Pseudohypertrophic muscular dystrophy	Progress of disease arrested, but only slight improvement owing to the absolute atrophy of majority of involved muscles
40	61	Glutamic acid 10-15	15	Amyotrophic lateral sclerosis	Bedridden at beginning, now able to walk gradually with cane; can use hands to sew for short time; more subjective than objective improvement
41	18	Glutamic acid 10-15	15	Subacute anterior poliomyelitic paralysis (right anterior tibial and medial quadriceps)	Uninvolved muscles greatly improved; no longer uses brace or crutches when walking; no change in paralyzed muscles
42	13	Glutamic acid 10-15	8	Progressive spinal muscular atrophy	Only very slight subjective improvement
43	3	Glutamic acid 10-15	9	"Friedreich's ataxia"	General improvement noted but typical clinical picture persists unchanged

METHOD OF STUDY

The creatine-creatinine metabolism of each patient was studied over a period of twenty days. The daily excretion of total creatinine, preformed creatinine and creatine in the urine were determined over a control period of five days. At the end of this time, the oral administration of from 10 to 15 Gm. of glycine or glutamic acid in water, milk or fruit juice was begun. No change was made in the adult patient's average diet, which usually contained approximately from 300 to 400 Gm. of carbohydrate, from 100 to 125 Gm. of protein and from 90 to 100 Gm. of fat. In children, a proportionately lower caloric diet, relatively higher in protein, was advised.

The effect of the ingestion of the amino acid on the excretion of the creatine bodies was studied in twenty-four hour specimens of urine for three similar periods of five days each. The total creatinine was determined by the method of Benedict and Myers,²¹ and the preformed creatinine was determined by the method

Group 3 (cases 18 to 34). Cases in which no increased creatinuria occurred or in which the increase was less than 50 per cent above that of the control period showed no improvement. Cases 18, 25, 31 and 34 were the exceptions.

In addition to the thirty-four cases in table 2 we have made observations in nine cases in which it was not possible to make urine studies. The results are shown in table 3.

COMMENT

The criteria for improvement in the patients were based on (1) the ability of the patients to perform the usual coordinated daily routine tasks of normal individuals, (2) the strength or lifting power of certain muscles or groups of muscles, (3) the number of times the muscles were able to contract against a load before complete fatigue resulted, and (4) the length of time fatigue lasted before the recovery of the muscle was complete. Muscular contraction may be induced by electrical stimulation, but we believe that voluntary contraction of the muscle by the patient is more convenient and beneficial and the cooperation of the patient is more easily obtained.

22. Folin, Otto: The Determination of Creatinine and Creatine in Urine, *J. Biol. Chem.* 17:469, 1914.

Throughout this work, practically all our patients noticed a remarkable improvement in their appetites, particularly a desire to eat protein in the form of meat. As a result of their increased food intake, practically all patients increased in weight. The stimulation of increased gastric secretion and possibly gastric contraction probably accounts for the increased appetite. Smith and Cowgill²³ recently confirmed the view held by others that increased dietary nitrogen, although not affecting the amount of pepsin, definitely increases the total amount of gastric juice secreted. Consequently, even in the cases in which no objective improvement

could be demonstrated, the patients noticed a distinct improvement in their general health. As a result of this feeling of improvement in general well being, the patients were easily induced to use their muscles. Of particular interest was the willingness of patients suffering from progressive muscular dystrophy to become very active, spending a greater part of the day "trying themselves out," so to speak, on various activities which were impossible before treatment was started.

As shown in table 2, nine out of the thirteen cases of progressive muscular dystrophy and pseudohypertrophic type of muscular dystrophy showed unmistakably marked improvement. A white boy, aged 6 years, under treatment at an early stage of this condition, apparently recovered complete physiologic function and anatomic normality, and gained about 15 to 18 pounds (6.8 to 8.2 Kg.)

over a period of ten months (fig. 1). His brother with a far-advanced stage of the disease has shown little or no improvement under treatment. In another instance, a Negro boy, aged 8 years, was bedridden at the time therapy was begun. After twelve months of therapy he was able to walk fourteen city blocks to school daily and to take part in all the games, not unlike any normal child (fig. 2).

However, four cases each of a far advanced type, although not showing any further progress of the disease, manifested no definite improvement of their condition. The probable reason for the negative results in these cases is that the majority of the important muscles were completely atrophied, and return to normal function was hardly possible. Milhorat⁹ and Tripoli and Beard⁹ have shown that the ability of the affected muscle to return to normal under this form of therapy depends on the state of the muscle fibers at the time the therapy is begun. Should pyknosis of the nuclei of the muscle fibers be present at this time the muscle fibers continue to complete degeneration and absorption. Therefore, after the therapeutic regimen has been com-

pleted either normal muscle tissue is present or completely degenerated muscle tissue is found. In a previous communication this phase of the problem together with a relatively recent theory of creatine formation is discussed in detail.⁹

We wish to make a note concerning the diet of these patients. Some workers reporting negative results in cases of pseudohypertrophic muscular dystrophy placed their patients on relatively protein-free diets while taking amino acids. All our patients took their normal amount of protein. In fact, the patients themselves desired and sometimes partook of high protein diets while taking amino acids. However, we endeavored to keep the protein intake as uniform as possible throughout the experiment. Reinhold and his co-workers¹⁰ also noted the beneficial effects of high protein diets with glycine.

The two cases of myasthenia gravis that have come under our observation have shown considerable improvement. Owing to the patients' residence many miles away from the city, urine studies were not possible. However, their improvement was easily demonstrable, the results confirming the observations of Boothby,¹⁶ Schmitt²⁰ and others. The use of ephedrine sulphate as an adjunct to amino acid therapy is of distinct value. Although these patients improved on glycine alone, we believe that the subsequent addition of ephedrine sulphate might enhance the beneficial effect of the amino acid.

The majority of cases in which the muscle atrophy was secondary to nuclear or peripheral nerve degenerations did not show the same improvement as in the cases previously mentioned. However, several of these cases had subjective and others some slight objective and subjective signs of improvement. Many of the beneficial effects noted by the patient can be accounted for by the increase in appetite, gain in weight and general feeling of well being. However, betterment in function of the unaffected muscles in the region of the completely paralyzed muscles increased the functional ability of the part, and, although the paralyzed muscles were not benefited, the functional capacity of the patient as a whole was improved.

A note concerning the use of amino acid therapy during the convalescent stage of poliomyelitis might be of interest. Gros²⁴ in a study of seven cases reported definite creatinuria which was increased with the admin-

Fig. 1.—Pseudohypertrophic muscular dystrophy in a white boy.

23. Smith, E. R. B., and Cowgill, G. R.: Proteins as Stimulants for Secretion of Pepsin, *Am. J. Physiol.* 105: 697 (Sept.) 1933.

istration of amino acids. His results led him to believe that the rate of atrophy of the paralyzed muscles was far less than that of control cases, and the muscle tone was comparatively well preserved. Also, those muscles in which only temporary loss of innervation occurred returned to normal more rapidly and more completely in the treated cases than in the untreated cases.

It seems that normal muscle metabolism depends in a great part on the proper function of the motor neurons comprising the so-called second trophic unit. When the latter is destroyed, normal creatine-creatinine metabolism of the corresponding muscle apparently becomes disturbed.

We have been unable to find any reference in the literature to studies on the creatine-creatinine metabolism in patients suffering from strabismus. One of the four generally accepted theories as to the etiology of this disease is "the muscular theory of strabismus," whose advocates maintain that the squint is due to an unbalanced activity of the rectus muscles, the eyeball being pulled to the side of the overactive muscle. In view of this theory, metabolic studies were carried out in patients affected by unilateral and bilateral strabismus. Their ages were 3, 6, 7 and 8 years, respectively. The duration of the disease varied from three months to six years. These patients were taking a relatively high protein diet, the principal constituent being meat. The average daily initial creatinuria in each case was 0.56, 0.74, 0.17 and 0.37 Gm., respectively. The slight increase above the physiologic average (0.087 Gm.) in creatine excretion in two of these children may be due to the dietary regimen. After amino acid therapy (from 10 to 15 Gm. daily), there was no increase in creatine excretion in cases 32 and 33 (table 2). However, in the other two (cases 31 and 34, table 2) the creatine excretion increased from 0.17 to 0.71 Gm. and from 0.37 to 0.91 Gm., respectively.

Careful ophthalmologic measurements two months after amino acid therapy was begun showed no significant changes from those observed before treatment. More cases are being studied in order to determine whether any uniformly consistent changes in their creatine-creatinine metabolism exists and in what manner, if any, amino acids would effect the metabolism.

SUMMARY AND CONCLUSIONS

1. A series of forty-three patients suffering from the following eleven different pathologic-clinical types of myopathies was studied as regards the effects of amino acid therapy: (a) myasthenia gravis, (b) progressive muscular dystrophy, (c) progressive pseudohypertrophic muscular dystrophy, (d) muscle wasting from disuse, (e) progressive spinal muscular atrophy, (f) subacute and chronic poliomyelitis, (g) multiple sclerosis, (h) amyotrophic lateral sclerosis, (i) muscular paralysis from jamaica ginger poisoning, (j) muscular paralysis from peripheral nerve section, and (k) Friedreich's ataxia.

2. Creatinuria was present in each of the ten different types of cases, except in one case of chronic poliomyelitis of fifteen years' duration.

3. The cases in which the average creatinuria increased from 50 to 200 per cent above that of the control period after amino acid therapy was begun, provided this increased creatinuria disappeared in a few weeks, showed both subjective and objective improvement.

4. Cases of the progressive nuclear type which showed about the same increase and decrease of creatinuria as those in the preceding classification showed only subjective improvement or merely an arrest of the symptoms.

5. Cases in which no increased creatinuria occurred or in which the increase was less than 50 per cent above that of the control period showed no improvement.

6. In general the cases classified as primary myopathies and myasthenia gravis showed distinct clinical improvement, except in a few cases of the former type in which the stage of the disease was advanced to the point of complete muscle degeneration.

7. Cases in which no metabolic studies were made conformed clinically in general to the foregoing statements.

8. The inclusion of amino acids in the diet serves to increase the appetite and body weight in the majority of patients with muscular dystrophy and muscular atrophy.

ABSTRACT OF DISCUSSION

DR. WALTER M. BOOTHBY, Rochester, Minn.: The authors have undertaken a big task in attempting to discuss in one paper the value of glycine and of glutamic acid in myasthenia gravis, in progressive muscular dystrophy and in progressive muscular atrophy. The three diseases are entirely different: the weakness of myasthenia gravis appears to be a characteristic fatigability of the muscles due apparently to an imperfect intermediary metabolism of the muscle protoplasm without much actual degeneration of the muscle fibers; progressive muscular dystrophy is associated with very definite and quite extensive muscle degeneration, while progressive muscular atrophy is primarily due to a change in certain nerve cells of the spinal cord. In a series of forty-six cases of myasthenia gravis treated with glycine and usually also with ephedrine, all but two responded favorably; thirteen patients are working, eight greatly benefited and doing light work; fifteen are moderately improved, and three have just started treatment. Only two failed to improve on treatment and gradually grew weaker and died; two improved on treatment but later abandoned it, grew worse and died; one died before treatment could be started; one improved greatly but contracted pneumonia and died, while one committed suicide after having definitely improved. In a series of twenty-seven cases of progressive muscular dystrophy there have been deaths but, on the other hand, no improvement has occurred that can be definitely assigned to the muscles involved. However, nearly all these patients feel better and can do more because the glycine apparently decreased the fatigability of the muscles not definitely involved in the disease; therefore it seems possible that the unfavorable progress of the disease may in some instances be slowed down or even stopped by the use of glycine and glutamic acid, but sufficient time has not yet elapsed to make such a result certain. This improvement in patients with progressive muscular dystrophy seems analogous to the decrease in fatigability that I have found to occur rather frequently following the administration of glycine to patients with a type of fatigability often seen in the tired business man or housewife and which is often an accompaniment of neurasthenia or so-called chronic nervous exhaustion. A series of progressive muscular atrophy treated with glycine is too small to permit evaluation of the results. The nature of the disease almost precludes any great benefit to the palsied muscles.

DR. K. K. CHEN, Indianapolis: The authors have demonstrated the importance of creatinuria for the diagnosis and prognosis of different types of myopathies. During the last few years I have watched the development of ephedrine and glycine therapy in the treatment of myasthenia gravis. Both drugs seem to be able to bring about improvement independently, but it is interesting to note that ephedrine, unlike glycine, will not produce creatinuria. This obviously shows that the two substances do not act in the same manner. For ephedrine the explanation seems to be simpler. The action of

ephedrine on the central nervous system has been well known. For example, in dogs or monkeys following cord transection, ephedrine increases the excitability of the reflexes. In myasthenia gravis, in which little is known of the etiology, the muscular atrophy probably takes place in this manner: The function of the muscle fibers is gradually impaired, which in turn accelerates further degeneration, and by such a process a vicious cycle is set up. The use of ephedrine seems to break up this vicious cycle and arrest the atrophic process by the increase of reflex excitability. With glycine, the explanation is relatively more complex. The conversion of amino acids to creatinine is well known. Whether or not glycine will stimulate the phosphagen formation is a question that requires further study. In the work of Dr. Tripoli and his associates, I notice that they also used glutamic acid, and I got the impression that they obtained equally good results. Monosodium glutamate has a meatlike taste and is widely used in China at ordinary meals as an appetizer. This salt can be easily manufactured from soy beans. If glutamic acid is confirmed to be as good as glycine, it may be a cheaper drug than glycine.

DR. HENRY A. MONAT, Dayton, Ohio: Two months ago I had a patient with very marked progressive muscular dystrophy. I read all the suggestions I could find in medical literature as to the treatment and decided to try the glycine. Then I reviewed some of the work done in Europe by Weiss on the physiology of heart muscle and the storage of glycogen and I decided to put my patient on a high carbohydrate diet and give him small doses of insulin. The man had all the symptoms elucidated in the paper. I took measurements of the muscles and found atrophy in the muscles of the thigh and the biceps. The patient could put his hands around his biceps when he came under my observation. His creatinine was very high. Under this high carbohydrate treatment with small stimulating doses of insulin (this is the seventh week of treatment) the increase in circumference around the deltoid was up to $1\frac{1}{2}$ inches. In conjunction with this high carbohydrate diet and no protein at all, I gave him physical therapy. I wonder whether this is not like one of those ideas in arthritis one gets enthusiastic about. My conclusion is that an individual should be studied as to his basal metabolism and blood chemistry and be individually treated, and one should not become overenthusiastic about one certain drug or one type of treatment.

DR. C. O. CHENEY, New York: Before this section last year, Drs. Harris and Brand reported the results of investigation that had been made by them for a number of years, including the treatment of some sixty cases of muscular dystrophy. This work has been continued, and I may say that our results do not agree with those that have been obtained by the present authors. With prolonged feeding of glycine we have not, in muscular dystrophy, been able to bring about any marked improvement in this rather large number of cases, which include both children and adults. It does seem that possibly the progress of the disease may have been arrested, but that is about all we have so far been able to bring about. The conditions in myasthenia gravis are different, and our results so far agree with those of Dr. Boothby.

DR. HENRY W. WOLTMAN, Rochester, Minn.: Myasthenia gravis tends to run a fluctuating course, and progressive muscular dystrophy is usually chronic and may come to a standstill for a number of years. However, I noticed that Dr. Tripoli and his co-workers mentioned another disease which usually ends fatally, with clocklike regularity, and that is amyotrophic lateral sclerosis. I should like to ask the authors how long these patients have been under treatment.

DR. HOWARD H. BEARD, New Orleans: I have nothing to add from the clinical point of view. I am interested mostly in the creatine metabolism. There are at least three different points of view here. First, it can be said that glycine and probably glutamic acid do increase creatine formation in muscle. That is a very important thing. Second, phosphocreatine gives energy for muscle contraction. Third, from the neurologic point of view, I think it is of interest that increased creatinuria is not usually obtained from the amino acids in neuromuscular conditions. That would seem to show the importance of the neuromuscular junction, the so-called second trophic unit in creatine formation from amino acids.

DR. CARLO J. TRIPOLI, New Orleans: The dosage we have used was from 10 to 20 Gm. a day. In children we administer 10 Gm., in adults 20 Gm. daily. Drs. Harris and Brand, who presented their work before this section last year, reported little or no benefit to their patients. In view of the conflicting results of their work, as compared with that of several others, it was our object to determine whether there was any relationship between the creatine studies and the clinical improvement, since some cases do improve and others do not. We have found that far advanced cases and many of the moderately advanced cases show no improvement whatever. The early cases, particularly children, have shown the most improvement. We have attempted to elucidate the good results obtained in some cases, and the bad or indifferent results observed in others, by metabolic studies as reported in this report. The two cases of amyotrophic lateral sclerosis which were mentioned by Dr. Woltman as improved are most interesting. A few of our patients with amyotrophic lateral sclerosis also improved. However, a great deal of their improvement we believed to be subjective, with slight definite objective benefit. A high carbohydrate diet, which has been used many times before in the treatment of such conditions, tends to increase muscle tissue. The increase in weight, however, is due principally to fat deposition and only in a slight degree to actual increase in muscle tissue. The use of amino acids in all our cases, with a few exceptions, has increased appetite. Previous work has shown that amino acids do also increase the amount of gastric secretion, although actual increase in pepsin secretion could not be demonstrated. The use of phosphates in conjunction with lactic acid in the treatment of these conditions has been tried, with some improvement noted after their administration. It would be interesting to use the three methods, high carbohydrate diet, administration of phosphates and lactic acid, and amino acids with three groups of patients in order to determine their relative efficacy. A group in which all three methods are used should incidentally be studied. Investigation of these phases of the problem is contemplated.

PROTEINS VERSUS THE CARBOHYDRATES

AN INQUIRY INTO THEIR GASTRIC DIGESTION

MARTIN E. REHFUSS, M.D.

Clinical Professor of Medicine, Jefferson Medical College of Philadelphia
PHILADELPHIA

Perhaps no time has been as propitious for the food faddist as this age of unrest. History records the fact that the food faddist has appeared in almost every recorded period of human history. Such methods die a natural death but sometimes not before accomplishing widespread injury and even death. The average faddist uses all the modern methods of illegitimate propaganda and modern high pressure salesmanship to sell his wares. He has not hesitated to select quotations from medical authorities, perverting them to his own end. The public, caught in cross currents of every sort of propaganda, has lent an ear, and the medical profession has generally been backward in approaching the problem, owing to the lack of information of a reliable nature which might controvert the evidence.

Not only have these reformers rehabilitated old doctrines but they have reached a position where some of them do not hesitate to prescribe for the invalid by mail regardless of the nature of the complaint. One searches in vain through the literature revealing several thousand contributions by research workers on diet and nutrition to find any real scientific work by these reformers. One of their dictums is the presumed

Read before the Section on Gastro-Enterology and Proctology at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 15, 1934.

incompatibility of proteins and carbohydrates, the presumption being that proteins require an acid medium for their digestion while carbohydrates require an alkaline medium. Man is an omnivorous animal. He subsists equally well on the high protein dietary of the arctics, the high carbohydrate regimen of the tropics and the most extraordinary food combinations of the temperate zones.

There is only one way to settle this problem and that is by the direct investigation of the behavior of these substances in the human stomach. Some years ago Dr. Hawk and I, together with a group of research workers, made the first complete studies of human gastric digestion in the untraumatized normal human stomach. The results of these studies were published from 1914 to 1920 in the *American Journal of Physiology* and represent a complete survey of the behavior of the normal stomach to every variety of foodstuff. In those studies it is apparent that human gastric digestion is by no means a hit or miss proposition. In more than 1,000 studies on 200 normal men we were able to show the gastric response on all varieties of foods and to correlate these so as to present in a general way the actual digestion of these substances. This was made possible by means of fractional gastric analysis, although previous studies were largely concerned with the observations of Dr. Beaumont on Alexis St. Martin and Penzoldt's classic observations on human gastric digestion.

We found that the normal human stomach is of several types, one we found to be of a relatively slow type and another of a rapid type of gastric digestion. Furthermore, the secretory response among healthy subjects could likewise be divided into groups, some showing a tendency to a low secretory output, others to a presumed normal and still others to a hyper-secretory type of response.

The most significant feature in these studies is the constancy of the type of gastric function. An individual belongs to one of these groups and, barring all accidents or disease, he maintains his gastric type. In those studies which included seventy-five complete experiments in meat digestion alone in twenty-five different subjects, we found that 100 Gm. of beef required, on the average, an evacuation time of two hours and thirty-five minutes in subjects of the rapid emptying type and three hours and twenty-five minutes in subjects with slow stomachs. Furthermore, the acid figures with meat were the highest of those encountered with any of the varieties of foodstuffs.

There were 120 studies on vegetables with twenty-four studies on potatoes prepared in ten different ways. Every form of carbohydrate is to be found in that series of studies. Tables 1 and 2 illustrate the behavior of the normal human stomach to the various varieties of food in the dietary and in themselves constitute an answer to the question as to whether the human stomach is able to handle carbohydrates and proteins. A fact that has apparently escaped the proponents of the carbohydrate-alkaline theory is that no carbohydrates are ingested which are not followed by a direct acid response on the part of the stomach; in other words, the normal digestion of carbohydrates is attended by the maceration of the carbohydrate in an acid medium before it is available for further digestion in the bowel.

In our normal subjects we found that, if we increased the quantity of beef ingested from 100 to 250 Gm., the evacuation time might be increased to five hours or more. In other words, evacuation time is dependent on

the articles ingested and the quantity of food. In any event, the average, normal individual has a gastric digestive time somewhere near four hours and rarely exceeding five hours during which no reasonable amount of fermentation can ensue. In 1929 Dr. Marcil and I¹ presented a paper on the gastric digestion of meat in health and in disease. In the diseased patient, as exemplified by the chronic invalid with cardiac or renal disease, blood dyscrasias and other conditions commonly encountered in medical ward service, we found the gastric digestion of meat somewhat impaired. In other words, a falling off in secretion and a slight increase in the evacuation time was, to our minds, evidence of some functional inefficiency on the part of the chronic invalid.

Food faddists point out that while the normal individual can digest practically everything within reason, and this is literally true, the same rule does not apply to the chronic invalid. For that reason in the last year I have carried out an investigation of the digestion of

meat representing a protein and potatoes representing a carbohydrate in a cross section of medical invalids ordinarily encountered in medical ward service. This series of studies represents almost every variety of medical problem ordinarily encountered in a medical ward service. Gastric, cardiac, renal, hepatic, pulmonary and infectious diseases are to be found among the number. I believe that no variety of chronic illness was missed in this group. These observations were carried on at the same time on successive mornings, and the food was carefully prepared and weighed and the following technique employed. Owing to the fact that, in my experience, the chronic invalid usually reveals a digestion time for meat of about four hours, I gave my patients for the first meal 100 Gm. of hamburger steak. Aspirations were commenced two hours after the beginning of the feeding and carried on until the stomach was clearly emptying both from the appearance of the specimen and by test lavage.

On the second day a meal of 100 Gm. of hamburger steak and 100 Gm. of mashed potatoes was given to

1. Rehfuß, M. E., and Marcil, G. H.: *The Gastric Digestion of Meat in Health and in Disease*, J. A. M. A. 92: 763 (March 9) 1929.

fifty patients. The technic was identical and the specimens were examined grossly and from the standpoint of total and free acidity. On the third day a meal of 100 Gm. of hamburger steak, 100 Gm. of mashed potatoes and 40 Gm. of fat in the form of butter was given to forty-three patients. This was the largest amount of fat which was considered advisable to use, larger amounts being unsatisfactory.

In table 3 the following points are significant: In fifty individuals given 100 Gm. of hamburger steak the average evacuation time was three hours and fifty-one minutes. This figure was somewhat similar to our previous studies on meat digestion, although in that group only 60 Gm. of meat was used while in the studies on normal individuals, 100 Gm. was administered. In this same group of fifty persons, steak and potatoes gave an average evacuation time of three hours and fifty-four minutes. There was actually three minutes' difference in the entire groups, representing the

three members of this group in whom the action of 40 Gm. of fat was studied together with 100 Gm. of meat and 100 Gm. of potatoes, the average evacuation time for the entire group was found to be about four hours and two minutes.

The acid figures in these studies are, of course, based on the observations after the two hour point. In my studies on meat in the healthy individual the acid figures from the two hour point on were practically always characteristic of the individual. I purposely delayed my studies until the two hour point so as to lessen, if possible, any fatigue on the part of the patient. Nearly 1,500 tests were made on free and combined acidity. In each instance, the acid figures from the two hour point to the end of digestion were added together and the general average was obtained. From that point all the general averages were combined and divided so as to obtain a general average for the entire group.

The result of these studies was briefly as follows: In the meat group alone the average total acidity was 69.7 and the average free acidity 28. In the meat and carbohydrate group the average total acidity was 76.2 and the average free acidity 33, while in the meat, carbohydrate and fat group, forty-three subjects in all, the average total acidity was 79.1 and the average free acidity 32.4.

To workers who are accustomed to studying gastric function it must be apparent that these secretory results are strikingly similar. The figures for the meat are almost the same as those for meat and carbohydrate. One could almost explain the slight discrepancy in acidity in the slight prolongation of time that occurs. The same thing is true regarding the figures encountered in the meat, carbohydrate and fat group. It is apparent from these figures that our original conclusion of 1929 is sustained; namely that the chronic invalid usually shows lower acid figures and slight prolongation of meat digestion. There is certainly no evidence to assume that any real change in acidity has taken place in the stomach cavity.

These observations, representing a year's work in a medical service, demonstrate better than any mere words can express the absolute inaccuracy of the statement that proteins and carbohydrates are incompatible in the stomach. They show without question that the stomach, even in the diseased individual, proceeds in orderly fashion to break up the meat fibers and initiate the first stage of protein digestion in the stomach. Furthermore, a study of these specimens proves beyond any question that there is an orderly, mechanical subdivision of carbohydrates so as to facilitate intestinal digestion. With the exception of those cases in which there is an actual stenosis or marked delay in gastric evacuation due to some mechanical obstacle, I am not familiar with any group of cases that show consistently any disturbance of protein and carbohydrate digestion. Eight of my cases showed no free acidity after the ingestion of meat and six of these eight showed no free acid consistently throughout all studies, while in two there was some free acid in either the second or the third type of meal.

I prefer to restrict my remarks strictly to my investigation, which shows beyond any question that the stomach, even in most disease conditions, is able to do its work efficiently and well. One of the outstanding features of normal gastric digestion was the observation that any type of food under appropriate conditions could be satisfactorily handled by the human stomach.

* FROM THE JOURNAL, March 9, 1929, p. 764.

difference in the average evacuation time between proteins and proteins and carbohydrates, despite the fact that 100 Gm. of carbohydrate food had been added to the dietary. With the exception of two instances in which unusual observations occurred, the data were strikingly uniform. A glance at table 3 will emphasize the actual figures obtained.

When one realizes that among these patients studied were those with nephritis, myocarditis, cholecystitis, angina pectoris, asthma, bronchiectasis and acute illnesses such as rheumatic fever and even pneumonia, one recognizes what a remarkable organ the stomach is from the standpoint of efficiency. This evidence clearly proves that any presumed incompatibility between protein and carbohydrate food, of which beef and potatoes, to my mind, were the best examples, is certainly not sustained. With the exception of one single individual in which certain other factors were apparent, there was no evidence in any of this group that the patients were unable to handle satisfactorily and in almost normal time a reasonable amount of protein and carbohydrate. The addition of fat, as is well known, causes a slight delay in evacuation. In forty-

The observations on the diseased person, other than those with diseased stomachs, are by no means as numerous, but at least these contributions represent a study of gastric function in chronic organic disease.

CONCLUSIONS

1. There is evidence to show that even in the diseased individuals of markedly different types there is

was free hydrochloric acid 28, total acidity 69.7; for the meat group, free hydrochloric acid, 33, total acidity 76.2; for the meat and carbohydrate group, free acidity 32.4, and total acidity 79.1; for the meat, carbohydrate and fat group, figures that can be readily explained by the increased test load used in the stomach but which are strikingly similar when one considers the method of examination.

no incompatibility between protein and carbohydrate digestion.

2. In fifty individuals suffering from various chronic diseases 100 Gm. of hamburger steak was digested in a little more than three hours and fifty-one minutes. On hundred grams of hamburger steak with 100 Gm. of mashed potatoes showed an average general evacuation time of three hours and fifty-four minutes; in forty-three of these persons a meal of 100 Gm. of hamburger steak, 100 Gm. of potatoes and 40 Gm. of butter showed a general evacuation time of four hours and two minutes.

3. The computed general acid figures from the two hour period onward in these three groups of studies

4. These studies emphasize the singular constancy of individual digestion, a point that we emphasized in our studies on normal gastric function.

5. There is no evidence either in the literature or in my investigation to lead me to believe that proteins and carbohydrates are incompatible in the stomach. The danger of such teaching based on a lack of scientific evidence is manifest, and while it may be true that many individuals overeat and are presumably better by a reduction of carbohydrates, the unqualified acceptance of such a teaching can lead to the occurrence of serious malnutrition as well as to a lighting of tuberculosis and old infections.

257 South Sixteenth Street.

ABSTRACT OF DISCUSSION

DR. J. EARL THOMAS, Philadelphia: I agree with Dr. Rehffuss as to the necessity for combating food faddists. The normal human stomach will handle almost anything and generally does best when it has an abundance and a variety of material to work on. However, I find it necessary to emphasize this point in teaching medical students, which indicates that the public is impressed with the claims of faddists and that some education is necessary. The observations of Dr. Rehffuss on the human stomach parallel in a way studies made years ago on animals by Cannon and by Pavlov. Pavlov noted that both carbohydrate and protein stimulate the secretion of gastric juice, protein more than carbohydrate, and fat least of all. In trying to reconcile these secretory studies with Pavlov's observations, I think that probably the meat acted as the chief stimulus in both the meat and the mixed diets. The increase in acid when carbohydrate was present was slight and probably accidental. The increase in acidity on addition of fat is surprising. In the observations on motility, the characteristic inhibitory effect of fat was noted. The amount of fat was small but was evidently sufficient to produce typical slight delay in emptying. Why should the well known inhibitory effect on secretion have failed to appear? Evidently the delayed emptying caused a retention of gastric secretagogues, and their prolonged action more than offset the inhibition of secretion due to the fat. The observations on the rate of emptying are particularly interesting, especially when it is noted that the stomach will empty 200 Gm. as rapidly as 100 Gm. of material. This suggests that the amount of material has less to do with the emptying time than the length of time it takes for the stomach to digest the food. From time to time I have emphasized the importance of the inhibiting effect on the stomach of fullness of the intestine. This study brings out another important factor, mentioned years ago by Cannon; namely, the condition of the food in the stomach. The extra carbohydrate apparently does not influence the emptying. It passes out when the protein is ready to pass out. How else is one to explain the fact that 200 Gm. of material is emptied as rapidly as 100?

DR. ERNEST H. GAITHER, Baltimore: Dr. Rehffuss proves by conclusive studies that definite types of gastric function are encountered in man and that in the majority of cases these types remain invariable throughout life. He strikes a withering blow at the chief claim of food faddists when he so clearly presents facts which he has definitely proved: "A fact which has apparently escaped the proponents of the carbohydrate, alkaline theory is that no carbohydrates are ingested which are not followed by a direct acid response on the part of the stomach; in other words, the normal digestion of carbohydrates is attended by the maceration of the carbohydrate in an acid medium before it is available for further digestion in the bowel." The important observation that during the normal period of digestion no reasonable amount of fermentation can occur will be of great assistance in dealing with aerophagic patients who insist that the distention and explosive eructations which they suffer are entirely dependent on fermentation, with the production of enormous quantities of gas. It is most difficult to convince these patients that they are laboring under a misapprehension; yet it has been my experience that such cases can be cured within twenty-four hours if sufficient time is devoted to emphasizing the facts proved by the author. The researches of Dr. Rehffuss are particularly dependable because of the manner in which they were conducted; that is, in the absence of operation and shock, thus revealing the condition without any manner of distortion. In proving that the acid figures after the ingestion of protein, carbohydrate and fat, separately and in combination, do not differ greatly, he furnishes facts of distinct value. Also when he conclusively proves, in researches on hospital invalids, that the stomach, even in the diseased individual, proceeds in orderly fashion to break up the meat fibers and initiate the first stage of protein digestion in the stomach that there is an orderly, mechanical subdivision in an acid medium of carbohydrates so as to facilitate intestinal digestion, he administers a crushing blow to the absurd theories of ignorant and dangerous food faddists and furnishes information of the highest therapeutic value.

DR. ANTHONY BASSLER, New York: It is interesting that there has been so much to do with this faddist idea in the last

three or four years. One just can't eat carbohydrates without taking proteins, and one can't eat any protein food without taking carbohydrates, and I have found that to be about the best answer to make to these patients. This idea was started years ago and it has been disqualified a number of times, yet now it is stalking around throughout the Eastern part of the country. It is quite a problem in practice. There seem to be a lot of people who prefer going along lines of least resistance, and, as Dr. Gaither has said, commonly very intelligent ones, and even in ill health, they prefer to go to disqualified men for those reasons, and especially those who have the advertising flair and who make immediate and unethical contacts with the public. Following Dr. Bloodgood's idea, however scientific physicians may be, they nevertheless have a responsibility to the public, whether the public appreciates it or not. The American Medical Association's coming out authoritatively by accepting such a paper as this for a prominent publication is not only a matter for the medical profession's scientific interest; it is a matter for the medical profession to take in a wholesale way and use in a propagandist sense to the public at large, because they, after all, are the sick people. They are the people that we are here to help, and while they may be stupid, we must remember that medicine is many years ahead of the public and should each one of us individually from this point on, as doctors and as representatives of this organization, take definitely the stand that there is nothing to this reanimated diet ghost of many years ago.

DR. FRANK SMITHIES, Chicago: I desire to support Dr. Bassler's remarks. New York is not the only place where there are people easily fooled. Food faddism is the sort of thing taken up usually by well bred women who have lost their incomes or by individuals of so-called high intelligence out of jobs who are backed by some high-sounding organization and who address women's clubs, Kiwanis, Lions and the like. They bring before such societies all sorts of queer feeding theories or "systems," establish courses and even sell books about their particular plans. Physicians should be, I think, militant against this sort of thing through hospitals, journals which reach the public and even through newspapers. Most of the "column writers" for newspapers are people who are type hungry, never had a practice and know nothing about medicine except from reading literature. Next in importance is Dr. Rehffuss's proof that, when a stomach is fed a meal which makes it do work, the acid figures are even higher than are those which it is customary to consider those of disease. The addition of fat, undoubtedly, as Munson and Cowie showed in the first issue of the *Archives of Internal Medicine*, delays the emptying time of the stomach, possibly because of its effect on stimulation of the liver and the gallbladder. The introduction of the fat factor changes the orderly progress of gastric digestion of proteins so that digestion of fat later can be taken care of adequately when the secondary products of protein and of carbohydrate digestion have become properly developed.

DR. MARTIN E. REHFUSS, Philadelphia: I was unable to read the complete paper or quote all the statistics and the figures. My experience has been like a great many of the experiences other physicians must have had. People have come to me with the ridiculous but apparently plausible theory that the proteins and carbohydrates don't agree in the stomach, and I knew well from studies covering almost eight years that this could not be true. They came back with the statement, "Well, that may not be true regarding a normal individual, but it is true regarding a sick person." I knew no place I could go for exact information regarding the subject, and I made up my mind that the only way to get the information was to get it myself. It took me a year to get the figures, and more than a week and a half to compile them, but these figures are the figures as they actually occurred in the ward patients at the Jefferson Hospital, and there is no evidence in that group which in any way suggests that that incompatibility may occur. Dr. Thomas had several interesting things to say. He said there was very little difference regarding the extra hundred grams of carbohydrate. That surprised me; but the truth is that the carbohydrates require generally a short evacuation time. Regardless of the fact that I added carbohydrate to the hundred grams of meat, it was the hundred grams of meat that dominated the so-called evacuation point. The question came up as to why

more acid. The difference was 0.03 per cent. That is practically negligible, but it is probable that the addition of carbohydrate causes the secretory power of the meat to continue longer than it would, although there may be also an intestinal factor. I quoted today the figures I have obtained. I have the tables and figures, which I think wouldn't be interesting simply because I can say that if any one comes to a physician with the statement that there is a gross incompatibility between carbohydrate and protein in the ordinary stomach, barring those cases in which there is allergy or other reason for the incompatibility, it is a falsehood and has no basis in scientific fact.

CARCINOMA OF THE CECUM: WHAT ARE THE CHANCES FOR CURE?

CLAUDE F. DIXON, M.D.

ROCHESTER, MINN.

The question to which I wished to find an answer was whether a patient who has remained well for at least five years following resection of a segment of the colon because of carcinoma may be classified as cured. Considerable doubt may rightly exist as to whether or not this question is answerable. Some persons apparently are inherently susceptible to the development of malignant processes. Examples are the multiple carcinomas, each of a distinctly different type, occurring simultaneously or consecutively in the same patient. Malignant lesions of the colon, for the most part, are single (except those which apparently arise from malignant degeneration accompanying multiple polyposis). Radical removal is the most effective means of relief, and while the ultimate outcome in many cases is disastrous, encouragement in the surgical treatment of carcinoma of the large intestine is spurred on by those persons who, once victims of the disease, have remained well for a number of years following resection.

After a patient has survived resection of a segment of bowel because of carcinoma, the remaining pertinent question of prognosis arises. Although it is impossible to foretell accurately the outcome in such a case, one may get some idea regarding prognosis in other similar cases by detailed study of those patients who are alive many years following removal of a carcinoma of the colon.

When one attempts to collect data on the curability of disease by determining the length of time a patient has lived—for example, following resection of the cecum for carcinoma—it is important to keep in mind that the patient who is apparently relieved of such a malady may succumb to another disease before sufficient time has elapsed to determine whether or not the original disease may recur. In other words, the normal death rate is to be kept in mind. In reviewing the patients who have been operated on at the Mayo Clinic from 1907 to 1928 inclusive, for carcinoma of the cecum, I have been able to collect 221 cases. In seventy-six cases, palliative measures only were possible; in 145 cases, resection was performed. Of these 145 patients, sixty have lived five years or longer following resection. This represents a 51 per cent survival, for five years or more, of patients who recovered from operation¹ (tables 1 to 4). All specimens removed have been

reexamined in the course of the present study and the grade of malignancy has been determined.

The three outstanding features with regard to the observations in these sixty cases are that practically all the patients had lost weight markedly, secondary anemia of varying degree was present, and a mass could be palpated in the right lower abdominal quadrant. Loss of weight and the finding of a palpable mass need no comment. Why the majority of patients suffering from carcinoma of the cecum become anemic may be a matter of conjecture. Alvarez and his co-workers² studied the varying degrees of anemia produced by carcinoma in different segments of the colon. They gave the opinion that absorption of products of bacteria, such as *Bacillus welchii* and organisms of the colon bacillus group, together with gradual loss of blood from the ulcerated lesion, account for the anemia. They further pointed out that in most instances apparently the mere presence of malignant cells does not in itself tend to produce anemia, for example, in cases of extensive carcinoma of the breast and fundus of the uterus the blood picture is usually normal, and it is not unusual following a short-circuiting operation in a case of carcinoma of the cecum for the blood picture at least to approach normal. The latter procedure, Adami has pointed out, relieves the pressure on the ulcerated portion and tends to prevent passage of bacteria into the lymphatic structures. These patients whose erythrocytes are markedly diminished in number, and the concentration of whose hemoglobin is decreased, may be thought to have a macrocytic type of anemia.

Obstruction is an additional phenomenon, a variable one, in cases of carcinoma of the cecum. When it is recalled that the content of the right half of the colon is of a liquid nature, it is easily understood why growths that occur in this segment of bowel may reach considerable size without the appearance of phenomena of obstruction, in contrast with those lesions which occur in the left half of the colon, where the content is semisolid and symptoms of obstruction are common.

Bargen³ has observed that, in general, carcinomas of the cecum, and to some extent those which occur elsewhere in the right half of the colon, may be divided into three groups from the standpoint of symptoms: (1) those in which anemia occurs, (2) those in which dyspepsia occurs and (3) those in which a mass is discovered by the patient or by the physician although there are no symptoms referable to the right lower abdominal quadrant. The vast majority of cases fall into the first group, which has been discussed. Patients often make complaint of symptoms which may at first lead one to suspect appendicitis or disease of the upper part of the abdomen, such as cholecystitis or even peptic ulcer. Those growths which occur in, or involve, the ileocecal valve usually produce sufficient dyspeptic symptoms, from obstruction, to make the diagnosis relatively easy. The lesion in cases of the third group can be said usually to be discovered by accident.

In this series of sixty cases, the duration of symptoms varied from a few weeks to many years. Undoubtedly many of the patients antedate by wide margins the onset of the condition for which they sought relief. It is an established fact, however, that malignant growths may be present in the colon for a considerable length of time, remaining operable and not metastasizing.

When the lesion has as its site the pouch of the cecum, localization by roentgenographic studies is sometimes extremely difficult.

Prognosis varies with metastasis and grade of malignancy. Involvement of lymph nodes was found in fifteen of the sixty cases. The finding of involved lymph nodes justifies a guarded prognosis; however, absence of this finding does not necessarily rule out regional extension or metastasis. Obviously a lesion of low

grade of malignancy justifies a better prognosis than one in which malignancy is of higher grade. The growths in the majority of the cases on which this report is based were of grade 2. Only three growths were of malignancy graded 4. It is interesting to note that one of the patients whose lesion was graded 4 was alive 22.2 years following resection, even though lymph nodes were involved.

The fact that all malignant growths of the cecum occur in relatively the same position has led to consider-

able speculation as to possible etiology. Wakeley and Rutherford⁴ offered the suggestion that carcinoma occurring in the cecum almost invariably begins opposite the ileocecal valve, and that biochemical trauma, produced by the alkaline fluids from the ileum, may be considered to be the cause. Consideration of etiology rather unexpectedly leads the investigator once more to the question of involvement of lymphatic structures. Craig and MacCarty⁵ in 1923 made a careful study of

involvement of lymph nodes in many cases of carcinoma of the cecum in which resection had been performed at the Mayo Clinic. They, too, emphasized that the posterior wall of the cecum was the most common site of malignant growths. They concluded that the situation of the growth explained why, in those cases in which involvement of lymph nodes had occurred, the posterior ileocecal group of nodes was the first involved. Metastasis of a generalizing nature apparently does not occur as frequently or as rapidly from carcinoma of the cecum as it does from carcinoma occurring in the more distal segments of the large intestine. Explanation of this is wanting.

Robertson⁶ and his co-workers found that if india ink was injected into the thoracic duct it passed first to the receptaculum chyli, thence downward to the lymph nodes along the left of the aorta. The signifi-

cance of this cannot as yet be interpreted. One possible explanation for the better results obtained in resection of the right half of the colon because of carcinoma may be that the lymphatic structures of the right half of the colon are not so widely distributed as are those of the left half. Therefore, when the cecum is resected, and necessarily the right half of the colon with it, the lymphatic structures are in closer proximity to the bowel than they are when the left half of the colon is resected. Hence they are more thoroughly removed in the former instance.

Judging from this series of sixty cases, the discrepancy in the duration of symptoms and the variability of symptoms account to a considerable degree for the inability to make an early diagnosis in a high percentage of cases of carcinoma of the cecum. Patients of middle age with unexplained, severe, secondary anemia should bring to mind, however, the possibility of a malignant condition of the right half of the colon. These features, and a history of intestinal disorder,

justify investigation of the large intestine as a possible source of trouble.

The surgical treatment of carcinoma of the cecum consists, obviously, of radical removal. The type of resection of the right half of the colon to be selected is largely a matter of individual opinion. Some surgeons of wide experience in colonic surgery prefer to perform the operation in one stage. Others are of the opinion that resection should be anticipated by ileocolostomy, allowing an interim of from two to four weeks. In some cases, particularly if patients are of advanced years and are markedly emaciated, the operation in two stages seems clearly justified. As previously pointed out, sidetracking of the intestinal current frequently is instrumental in bringing about marked general improvement and in decreasing the anemia.

The patient with a malignant lesion of the cecum, whose general condition is good, may well be a fit subject for resection in one stage. Recently it has been our practice at the clinic to employ the operation in one stage in treatment of those patients of middle age whose loss of weight has not been marked. The accompanying anemia, unless extremely severe, usually can be remedied by blood transfusion twenty-four hours before operation.

The choice of the type of anastomosis to be made between the ileum and the transverse colon, following resection of the right half of the large intestine, depends again on the individual surgeon and on his experience with the methods he advocates. Moynihan, in resections of the right half of the colon, employed for a time end-to-end anastomosis between the ileum and the transverse portion of the colon. He later chose to close both the ends of the ileum and colon and to make side-to-side anastomosis. The use of the button in anastomosis following resection of the right half of the colon has been proved to be an effective method. From the standpoint of safety, lateral anastomosis seems best because there is less danger of impairment to the vessels that supply the site of anastomosis. The end-to-side anastomosis has, however, gained favor with some. Lahey has advocated a modified Mikulicz procedure for removal of growths of the right half of the colon. His results from the use of this method are excellent.

Temporary ileostomy of the Witzel type serves as a worth while safeguard against distention from intestinal gases in any type of intraperitoneal resection of the right half of the colon.

The preparation of patients who are to undergo surgical procedures on the large intestine has lessened appreciably the mortality rate and also has made for a more uneventful convalescence. In brief, such patients

are hospitalized four or five days before operation. During this period, their diet consists of 2,800 calories a day, of foods of lowest residue, principally carbohydrates, such as candy, fruit juices, custards, gelatin, rice, eggs, thin soups and broths. Seventy-two hours before operation, an intraperitoneal injection of vaccine, prepared from streptococci and organisms of the type of colon bacilli, is carried out. Although this procedure does not prohibit entirely the occurrence of peritonitis, it has lessened markedly the incidence of peritonitis.

SUMMARY

Sixty cases of carcinoma of the cecum, in which the patients have survived from five to twenty-two and two-tenths years after operation, form the basis of this report. In three cases the grade of malignancy was 4, in ten cases the grade was 3, in six cases it was 1, and in the remaining forty-one cases it was 2. In fifteen of the sixty cases, lymph nodes were involved.

ABSTRACT OF DISCUSSION

DR. JEROME M. LYNCH, New York: Dr. Dixon's paper is of particular value, since he calls attention to a little known phase of the carcinoma problem; namely, the high percentage of long term survivals or five, ten and fifteen year cures. I commend the note of optimism in his presentation, for it is essential to convince the profession that carcinoma of the cecum and, indeed, of the rest of the large bowel yields a high percentage of cures if handled with surgical boldness. I am impressed in my daily work with the attitude of hopelessness so prevalent among internists and general practitioners faced with carcinoma of the colon and intestine. They must be informed of such results as Dr. Dixon has presented and must be shown that the prognosis of cancer of the colon is very different from that of carcinoma of the esophagus. In these days of what might almost be called radiotherapeutic propaganda, it is refreshing to see what can be accomplished by plain surgery. I am not opposed to radiotherapy, but I remain unconvinced of its value in neoplasms of the colon and rectum. It is striking that little if any advance has been made in making early diagnoses in this field. There is too great a tendency to think of colon cancer in terms of pain, obstruction, constipation and diarrhea. It must be emphasized and taught that an indefinite dyspepsia, a loss of appetite and strength or an obscure anemia are much more common as the early symptoms. I feel that progress would be made if the middle aged patient with dyspepsia was first subjected to a fluoroscopic examination of the colon.

DR. J. W. THOMPSON, St. Louis: In the face of recurrence of carcinoma of the right half of the colon, the situation is not entirely hopeless. To prove this contention I want to summarize the histories of two patients in whom recurrence took place some years after the resection of the primary growth. Whether these were true recurrences or were additional, new primary lesions is debatable. Both of these patients were elderly men. One of them lived eight years before demonstrable recurrence or secondary growth was demonstrated. The other developed an additional carcinoma at some distance from the primary lesion fourteen years after resection of the first growth and in this patient there was metastatic involvement of the regional lymph nodes at the time of the primary operation. It has now been eight years since the resection of the second carcinoma of the right half of the colon in one patient and four years since the resection of the carcinoma in the second patient, which occurred slightly farther down the bowel. I want to emphasize this point because it brings out the necessity of detailed clinical follow up of these patients. They must be reexamined from time to time and this reexamination must include careful checking by guaiac test of the occult blood reaction in the stools as well as proctosigmoidoscopy and the barium enema examination including fluoroscopy and roentgenography. Recexploration of the abdomen is warranted, in selected cases, despite recurrence of malignant growths.

NEURITIS

STANLEY COBB, M.D.

AND

HOWARD C. COGGESHALL, M.D.

BOSTON

Neuritis is common; it is easily recognized, yet few conditions are so often inadequately diagnosed. The trouble is not that the physician does not name the pathologic condition correctly but that he is too willing to be satisfied with the mere naming and thereat cease his investigations. It seems important, therefore, to summarize at this time the status of knowledge concerning the etiology of neuritis so that the cause in each case may be more correctly understood and the treatment more appropriate. During the last fifteen years epidemics of encephalomyelitis, the advancing knowledge of dietary deficiency, and new industrial poisons have all added valuable facts to aid in the understanding of neuritis.

Many textbooks give excellent descriptions of the different types of neuritis, but the material is widely scattered under various headings. Of the monographic studies the best are probably by Ross and Bury¹ in 1893, by Harris² in 1926 and by Collier³ in 1932. A thorough discussion of the literature would be interminable, and even a complete bibliography would be too long to print in this connection; so, for each category of neuritis discussed, we have given one or two selected references, often the earliest one, as the first description is usually the best.

The term "neuritis" as used in this paper is to be understood as meaning a painful, degenerative (often inflammatory) process in any part of the peripheral neuron. It seems unnecessary to introduce the word "neuronitis," as other authors⁴ have unsuccessfully tried to do, because the syllable "neur" sufficiently indicates that it is the neuron that is involved. Rarely, if ever, are pathologic changes found in one part of a neuron alone; if the axon is primarily affected there is soon a change in the nerve cell, and vice versa. When the primary pathologic condition is localized at one part of the course of a nerve fiber, its position is often indicated by the symptomatology; eventually, however, the whole neuron suffers.

For example, in figure 1 an acute inflammation of the ventral horn cells at *A* gives the picture of anterior poliomyelitis with paralysis and later atrophy of the muscle (*M*); at the onset there is evanescent tenderness along the whole axon while the process is acute. Inflammation of the dorsal root ganglion (*D*) gives the contrasting picture of herpes zoster with a skin eruption and localized pain at *S*.

Chronic syphilitic inflammation, however, at *D* and *R*₁, causes locomotor ataxia, with intermittent pain, great loss of muscle sensibility and of skin sensibility to a less degree. Root lesions at *R*₁ and *R*₂ could be predominantly sensory or motor, but usually inflammation of the roots ("radiculitis") involves both elements to a greater or less degree (*R*). The fact that the location of the main lesion is in the root is ascertained

by the segmental distribution of the peripheral symptoms. Similarly, inflammation, degeneration, tumor or trauma of a peripheral nerve (*N*) is recognized by the well known anatomic distribution of the nerve fibers making up each nerve trunk. Local injuries to terminal filaments in skin (*S*) and muscle (*M*) occur, of course, but either they are so local as to be insignificant or else they spread upward and involve the rest of the neuron, as in rabies, tetanus and rarely in local diphtheritic infection.

Thus our definition of neuritis (briefly stated) should be modified to read: "A painful,⁵ degenerative process in any part of the peripheral neuron causing a functional loss, which, according to the anatomy involved, may be sensory, motor or mixed."

From the etiologic point of view the causes of pathologic changes in a peripheral neuron are so multifarious that a discussion of each would be tedious and confusing. The principal causes of neuritis have, therefore, been arranged in table 1 (the bibliography being given in table 2). This is indeed somewhat arbitrary, but the table presents the relationship as it is known at the present time. Obviously this is imperfect, because the etiologic agents in several of the categories are as yet entirely unknown.

The principal division into "general" and "local" is fundamental in that it separates out the less important group of unilateral disorders that attack one nerve locally, from the great group of systemic disorders that cause severe symptoms in several nerves, usually bilaterally and often symmetrically.

The "local" group is called relatively unimportant for two reasons. In the first place, the etiology is obvious, as in the mechanical cases in which surgical or medical therapy can be instituted by the appropriate physician; secondly, the symptoms are often trivial and transitory. Of course some cases of local paralysis may be severe and long lasting, and local infection of a nerve may be painful and dangerous. By and large, however, the groups under "general" are clinically more important and endanger life more than the "local" types, which are mainly seen in "outpatients," and in military and tropical practice.

REPORT OF CASES OF GENERALIZED POLYNEURITIS

To show how this table may be of use in diagnosis, some illustrative cases are here reported and discussed.

CASE 1.—*Acute infectious (febrile) polyneuritis.* An Italian girl, aged 17 years, single, admitted to the Neurological Service of the Boston City Hospital, Dec. 24, 1932, complained of weakness of the legs for two weeks. One month before admission she had an acute infection of the upper respiratory tract, accompanied by sore throat, epistaxis, fever, headache and nausea. The acute symptoms improved after a week, except for occasional headaches, anorexia and generalized weakness. December 14 her legs suddenly became weak and she collapsed. She was unable to walk and was carried to bed. There was a tingling sensation in the feet. Two days later she noticed stiffness of the left side of the face, inability to close the left eye, and "pins and needles" sensation in the finger tips. About this time she suffered from severe headaches and vomited; she had pain between the shoulders, tenderness of the calf and thigh muscles, insomnia and urgency of urination.

In childhood she had measles, chickenpox, scarlatina, pneumonia and diphtheria. She never had poliomyelitis, rheumatic fever, chorea, pertussis or a venereal disease. The family history was not significant.

On physical examination, December 25, the patient was well developed and nourished; she weighed 110 pounds (50 Kg.)

5. The element of pain may be extremely mild and evanescent, as in lead poisoning and infantile paralysis.

From the Department of Neuropathology, Harvard Medical School, and the Neurological Unit, Boston City Hospital.

4. Barker, L. F.; Cross, E. S., and Irwin, S. V.: *Am. J. M. Sc.* 159: 157 (Feb.) 1920.

and was 5 feet 6 inches (170 cm.) tall. She was resting comfortably in bed, complaining of inability to close the left eyelid, burning of the eyes, lacrimation, pain between the shoulders, numbness of the fingers and toes, urgency of urination, tenderness of the biceps, hamstring and gastrocnemius muscles, and extreme weakness of the legs. There was complete paralysis of the left side of the face and slight weakness of the right side of the face; the face and neck were flushed. The pupils were equal and reacted to light and in accommodation. Other cranial nerves were normal. The tonsils were red and swollen and the palate and tongue were normal. The lungs were clear and resonant throughout. The heart was not enlarged; there were no cardiac murmurs; the pulse was 120 and the blood pressure 120 systolic, 82 diastolic. The abdomen was normal, except for weak musculature of the wall and absence of abdominal reflexes. Reflexes of the biceps, triceps, patellar and achilles tendons were absent bilaterally. The plantar reflexes were normal. Any manipulation of the legs that tended to stretch the sciatic nerves caused intense pain. The legs were weak, especially the left. The grip of the hands was weak. No sensory changes were present except hyperesthesia of the feet, and paresthesia of the fingers and toes.

Examination, Jan. 7, 1933, showed that the patient was well oriented, mentally clear and cooperative. There was a com-

muscle tenderness in the left biceps brachii and thigh muscles. Earlier in the day she had slight epistaxis, which required a nose pack.

January 28, the left facial muscles were still weak but she was able to close the left eye. She did not blink the left eye as often as the right. The legs were much stronger, and there was no drop foot.

January 30 there was slight epistaxis. February 2, paresthesia of the fingers had disappeared; she was able to walk. February 5, neurologic examination showed a slight left facial weakness, the left palpebral fissure wider than the right; all muscles of facial expression were active. The face had more expression and had lost the "ironed out" look. The biceps, triceps, patellar, achilles, and abdominal reflexes were present, equal and active; plantar reflexes were normal. There was marked muscle tenderness over the right calf and thigh and the left biceps brachii muscles. Walking brought out a slight weakness of the right leg. February 7 an accurate perimetric test confirmed the finding by rough test of a slight peripheral concentric constriction of the visual fields noted earlier. February 8, left facial weakness was still present, especially on volitional expression. There was pain with anterior flexion of the neck. The calf, thigh and left arm muscles were still painful. Knee jerks were hyperactive and equal; ankle jerks

TABLE 1.—Principal Causes of Neuritis

Neuritis					
Generalized Polyneuritis			Localized Neuritis

plete left facial paralysis and a slight flattening of the right side of the face. The neck was not stiff on anterior flexion, but this caused a sharp pain between the shoulders. The arms were weak and showed a fine tremor when held in extension. Marked weakness and impaired voluntary movements were noted in the legs, especially the right; subjectively the left leg was weaker. There was tenderness in the calf, thigh and biceps brachii muscles. Sensory examination showed tenderness of the sciatic and brachial nerves; areas of diminished sensation to touch and pain were found on the flexor surface of the arms. There was diminished vibratory sense below the knees. All tendon and abdominal reflexes were absent. Plantar responses were diminished. The pupils were regular and reacted well in accommodation and sluggishly to light. January 14 the patient was presented at a conference before Drs. Brouwer, Ayer, Crothers, Fremont-Smith, Putnam and Merritt. Dr. Cobb's examination showed a complete left facial paralysis, weakness of the right side of the face, fine tremor, incoordination and weakness of the arms, weakness of the legs, and painful sciatic nerves; there were absent reflexes of the upper extremities, abdomen and lower extremities; the Babinski sign was absent; the heel-to-shin test was poorly performed. There was no demonstrable sensory loss except loss of vibratory sense in the lower legs. In his discussion he linked up the neurotropic and dermatotropic diseases, showing a definite relationship between dermatitis, myositis, neuritis, neuronitis and myelitis. It was agreed that the case was one of infectious polyneuritis, probably due to an unknown filtrable virus.

January 25, the left facial muscles showed weak movements. She still complained of headache, slight vertigo and slight

were present but decreased. She weighed 106 pounds (48 Kg.), a loss of 14 pounds (6.4 Kg.) since the onset of her illness.

Laboratory Data: Urinalysis showed occasional faint traces of albumin and a few white blood cells on numerous examinations. There were no casts or red blood cells. White blood counts were: Dec. 24, 1932, 11,400; Jan. 14, 1933, 13,000; January 28, 12,700, and February 7, 8,500. The red blood counts were normal. Hemoglobin, December 24, was 85 per cent. The differential count was 77 per cent polymorphonuclears, 21 per cent small lymphocytes, and 2 per cent monocytes. Nonprotein nitrogen determinations on December 24 and 25 and on January 31 were 33, 33 and 17 mg. per hundred cubic centimeters, respectively. Fasting blood smear, January 31, was 76 mg. per hundred cubic centimeters. Blood culture showed no growth. The Kahn and Wassermann tests of the blood were negative. The spinal fluid readings are given in table 3. Roentgenograms of the skull were negative. Electrical reactions on February 4 showed a partial reaction of degeneration of the left facial nerve. An electrocardiogram on February 10 showed sinus arrhythmia and a pulse rate of 90.

At the time of discharge, February 13, the patient had only a slight weakness of the right leg. An examination two months later, in the outpatient department, revealed that she had made a complete recovery.

The diagnosis was infectious polyneuritis.

This type of case, although described by Osler⁶ as early as 1892 and by Ross and Bury¹ in 1893, was

⁶ Osler, William: *The Principles and Practice of Medicine*, ed. 1, New York, D. Appleton & Co., 1892, p. 777.

not well recognized as a clinical entity until the World War. Then Patrick,⁷ Kennedy⁸ and Bradford⁹ all observed cases of acute infectious neuritis that were severe and often fatal. Many of these cases occurred during the period when "lethargic encephalitis" was epidemic. Moreover, the more severe cases showed

INFECTIOUS

- Diphtheria (Walshe, F M R Lancet 2:232, 1918).
Tetanus (Wilson, George, and Hadden, S B J A M A 98:123, 1932).
Streptococci (Orr, D, and Rows, R G Brain 36:271, 1914).
Leprosy (Monrad Krohn, G H Neurological Aspect of Leprosy Christiania, D Dybwad, 1925).

evidence of myelitis, such as exaggeration of the deep reflexes during convalescence and Babinski's sign. Some showed cranial nerve paralyses difficult to differentiate from those of encephalitis. The principal reason for segregating these cases into a neuritis group is that the disease begins with tenderness of the muscles and nerves, flaccid paralysis and paresthesia. If it were not that the tenderness persisted for weeks, the patients might well be thought to have infantile paralysis. In fact they do have, pathologically speaking, a certain amount of acute anterior polymyelitis, but the axon appears to be more severely involved than the nerve

cell, which obviously does not die but is able to survive and produce a new axon in those cases in which recovery occurs. Bradford and his co-workers even isolated a virus by using the Flexner-Noguchi method and transmitted this to monkeys. Since this work has not been adequately confirmed, one cannot say that the etiology of this disease is known. Nevertheless, the clinical picture, the epidemiology, the fact that patients with encephalitis sometimes have a similar neuritis, and the few autopsies which show acute changes in the white and gray matter of the central nervous system, are pieces of evidence which, taken together, point to the tentative classification of this disease with the known "virus diseases." Infantile poliomyelitis and epidemic (lethargic) encephalitis have already been mentioned. "Landry's paralysis" is a name frequently and loosely used; the original description probably referred to cases of this acute infectious type; most cases now diagnosed as "Landry's" are fulminating examples of ordinary infantile paralysis. On the whole, as Taylor¹⁰ urged on many occasions, it is best to discard the term entirely.

Other known virus diseases that may painfully paralyze the peripheral neuron and hence can be said to produce neuritis are measles, smallpox, herpes zoster and parotitis. The last is rare, but occasional cases occur in which inflammation of the parotid gland, not unlike "mumps" in onset, is accompanied by a widespread polynucleuritis and often iritis.

In summary, one may characterize acute infectious polynucleuritis by the acute or subacute onset with fever, anorexia, fatigue and weakness. Then flaccid paralysis of the extremities appears, usually following numbness and tingling of the digits; usually there is facial weakness and occasionally complete bilateral facial paralysis and slight sphincter disturbances. There are no mental changes. Examination of the patient reveals a widespread muscle weakness, or even complete flaccid paralysis, with absence of tendon reflexes; the neck may be slightly stiff and painful on anterior flexion.

Fig. 1.—Diagram of a spinal cord segment and peripheral nerve with the sensory end-organ (S) and the motor endings in the muscle (M). The various parts of the nerve infected in neuritis are described in the text.

There is marked nerve and muscle tenderness. Sensory examination shows diminished vibratory and position sense and, occasionally, diminished cutaneous sensibility of the hands and feet. There is a slight leukocytosis, and a low fever in the beginning of the disease. The spinal fluid shows no constant changes; it may be normal and may show an excess of protein and a few leukocytes.

CASE 2.—Bacteriotoxic polyneuritis from pansinusitis. A white man, aged 34, a laborer, admitted to the Neurological Service of the Boston City Hospital, Dec. 15, 1931, complained of weakness and dizziness of four weeks' duration. His illness started six weeks before entry to the neurologic ward, with an acute attack of swelling and tenderness of the right cheek.

He had had slight fever throughout the course of the disease. He was admitted to the aural service, Nov. 24, 1931, and the right antrum was opened and drained. He was discharged November 26. Twelve days later he noticed thickness and indistinctness of speech. This was soon followed by aching pains behind both eyes, and "pins and needles" sensation in the hands and feet. The fingers and toes became numb and cold. The legs became weak and clumsy. By December 10 the numbness of the feet had gradually ascended to the hips. He also complained of loss of weight, anorexia, constipation, gas on the stomach, difficulty in swallowing, and occasional regurgitation of food through the nostrils. The weakness of the arms and legs gradually progressed until he was confined to bed, unable to walk or care for himself. He was readmitted, December 15.

Fig. 2 (case 1).—Bilateral facial weakness more marked on the left. In A she was asked to raise her eyebrows and look up. In B she was asked to close her eyes and smile, and in trying to do this she smiled spontaneously.

The past history and family history are not remarkable.

On physical examination the patient was well developed and poorly nourished, lying in bed acutely ill. There was nasal discharge and tenderness over the right frontal sinus and antrum. The viscera and heart were normal.

On neurologic examination the cranial nerves were normal except for the fifth, eighth and ninth. The fifth showed loss of sense of pain, temperature, and touch on the right cheek. Hearing was reduced to one third on the right; the Weber test was referred to the right. The soft palate was weak, and the gag reflex was absent. The voice was thick and indistinct. In the visual fields the fundi and pupils were normal. Motor system: There was a generalized weakness in all extremities; he was unable to stand; he raised his arms feebly. There was no complete paralysis of any muscle group. The muscles of the legs showed conspicuous atrophy. Sensory system: Examination showed a hypesthesia for pain, temperature, and light touch over "glove and stocking" areas of both hands and feet. Vibratory sense was diminished in the lower extremities. Position sense was lost in the fingers and toes. There was tenderness of the muscles and nerves in the lower extremities. Reflexes: The triceps, biceps, radial, patellar and achilles tendon reflexes were absent. Abdominal and cremasteric reflexes were absent. The plantar responses were normal.

Urinalysis showed no albumin, sugar, blood cells or casts. Examination of the blood showed: hemoglobin, 85 per cent; red blood cells, 4,870,000; white blood cells, 10,700; differential count and smear, normal; blood nonprotein nitrogen, 35 mg.; the blood Kahn test, negative.

Lumbar puncture, Dec. 10, showed no abnormality. Nasal culture, Jan. 20, 1932, was positive for *Streptococcus haemolyticus* and *Staphylococcus aureus*. Blood cultures were all negative. Tests on the urine for arsenic and lead were negative. Roentgenograms showed cloudiness of the right antrum.

January 22, the patient was transferred to the aural service, where a radical sinus operation was performed on the right side. There was a normal convalescence.

February 12, the patient showed rapid improvement in the strength of the hands and arms. March 2, the patient was able to get out of bed and sit up in a chair. March 8, he was discharged home; he was able to walk with the aid of crutches. There was no weakness except that of the legs.

The social service in the follow up reported that on April 1 he began work carrying ice and has been apparently perfectly well up to July 1, 1933.

10. Taylor, E. W., and Clarke, J. E.: *J. Nerv. & Ment. Dis.* 27: 177, 1900. Taylor, E. W., and McDonald, C. A.: *The Syndrome of Polyneuritis with Facial Diplegia*, *Arch. Neurol. & Psychiat.* 27: 79 (Jan.) 1932.

In this case, at first glance, it seems obvious that the polyneuritis was caused by a chronic focal infection. The time relations seem right: five and a half weeks of severe sinusitis before the neuritis. Moreover, the fact that relief followed radical drainage seems to clinch the argument. As in all complex situations, however, one must look for all the possibilities, and here it could be argued that dietary deficiency was a factor. This patient had a long illness, with anorexia, occasional vomiting, constipation and marked loss of weight; these data cannot be overlooked, and it must be admitted that lack of proper vitamin ingestion may have been important in the etiology. Perhaps more than one factor is needed to produce polyneuritis, for, if prolonged infection alone could easily produce it, the syndrome ought to be much more common than it is. In fact, the few cases we could find in the records of the neurologic service that seemed obviously related to focal infection all showed a remarkable loss in weight.

Probably local abscess formation, due to pyogenic organisms, with a subacute course is the commonest cause of the entity we are calling "bacteriotoxic polyneuritis." One subgroup would be dental abscesses, especially the apical infections with streptococci. Many cases have been seen in which dental caries was the

a rôle. For example, in the days when typhoid was common and was treated by virtual starvation, a condition not unlike beriberi was a common result. Indeed, the moral to this tale is that in all chronic illness, especially when subacute and chronic focal infection plays a rôle, it is imperative not only to keep up a reasonably high caloric content in the diet but to see to it that plenty of each vitamin is being ingested.

CASE 3.—Neuritis with alcoholic pellagra. A man, aged 40, single, a World War veteran, admitted to the Neurological Service of the Boston City Hospital, June 20, 1933, complained of weakness, inability to walk, numbness of the feet and hands, and painful soles of the feet for one month. This illness was an acute exacerbation of a condition that he had had for the past six years. During this time he had lived a haphazard existence without doing work for self support or accepting aid from charity organizations. His food consisted of what he could get by begging or by imposing on friends. His dietary habits had been irregular. Many times he had periods of two days' starvation. A chunk of meat, bread and coffee would make up his usual noonday meal. He disliked vegetables and made no effort to get them. He occasionally ate potatoes. In spite of his difficulty to obtain proper food, he was able to get plenty of alcohol and "moonshine," and he consumed from 2 pints to 2 quarts daily with occasional respites.

A year and a half before he was in a good state of health and weighed approximately 230 pounds (104 Kg.); on admission he weighed 160 pounds (73 Kg.). He said that lack of food and appetite was responsible for the loss in weight. For the past six weeks he had had frequency of urination, numbness of the hands and feet, stiffness of the muscles and anorexia. There was an indefinite history of vomiting and diarrhea. One month before his legs were so weak that he was confined to bed.

The past history showed that he had had three admissions to the Chelsea Marine Hospital for treatment of the same syndrome. On each admission he had been discharged as cured after a stay of from four to five months. There was no history of syphilis. There had been no other significant illness.

On physical examination, June 20, the patient was well developed and emaciated; he was lying in bed, unable to walk. His face was rough and covered with a heavy growth of beard. The skin was rough and dry. There was a scaling dermatitis of the hands and feet with a line of demarcation at the wrists and ankles. There was marked dental caries, a foul breath, a large tongue without atrophy or beefy color, and an injected throat. The apex beat of the heart and the left border of dullness measured 9.5 cm. from the midsternal line. There were no thrills or murmurs. The pulse was regular; the blood pressure was 120 systolic, 76 diastolic; the pulse was 80. The peripheral vessels showed no evidence of arteriosclerosis. The chest wall showed wasting. The lungs were resonant and clear. The abdominal wall was held rigid, but no abnormality was made out. The genitalia were normal. The extremities showed a pellagroid dermatitis, emaciation, weakness and soreness of the muscles, voluntary rigidity, and bilateral drop foot.

Neurologic examination showed mental confusion, fair orientation and poor memory. There was a fine unsustained horizontal nystagmus. The cranial nerves showed no other abnormalities. Motor system: There was a generalized muscular weakness and wasting; this was most marked in the small muscles of the hands, forearms and legs. There was bilateral drop foot. He was unable to walk because of weakness of the legs and soreness of the feet. There was a fine tremor of the arms. Coordinated movements of the arms and legs were poorly performed. Sensory system: There was a "glove and stocking" loss of perception of pin prick, temperature and light touch. Gentle pressure to the soles of the feet, calf muscles and thighs caused shooting pains. Pressure on or stretching of the sciatic nerve caused severe pain. Vibratory and position sense of the arms and legs were greatly diminished. Reflexes: The biceps, triceps and radials were present, active and equal. Knee jerks were present, but diminished. The achilles reflexes were absent. The abdominal, cremasteric and plantar reflexes were absent; there was no Babinski reflex. Sympathetic: The pupils reacted sluggishly

TABLE 3.—Cerebrospinal Fluid Readings

Date	Initial Pressure	Lymphocytes	Red Blood Cells, per C. mm.	Protein, Mg. per 100 Cc.	Sugar, Mg. per 100 Cc.	Chloride, Mg. NaCl per 100 Cc.	Colloidal Gold	Wassermann
12/24/32	130	5	42	80	91	702	0000000000	Negative
12/25/32	200	5	5	87	67	726	1120000000	Negative
1/10/33	130	3	10	80	0001111100	Negative
1/24/33	105	13	176	55	0000000000	Negative
2/ 2/33	120	3	0	28	74	732	0000000000	Negative

only infection discovered, and some of these patients have improved conspicuously after tooth extraction and pus drainage. Such evidence, however, must be regarded skeptically; infected teeth are too common and polyneuritis cases are too rare to be lightly linked as cause and effect. Other factors must be sought.

It is important here to mention the analogy to the clinical syndrome called "polyarthritis"; there probably is a significant relationship. A great many cases of mild polyneuritis associated with arthritis¹¹ are never seen by the neurologist because the internist treats the main symptoms and knows that, if he cures the joints, the nerves will probably follow suit. Involvement of the muscles frequently occurs with arthritis, but myositis is rarely diagnosed, although lame, stiff and tender muscles are one of the chief complaints. All too frequently neuritis is overlooked, even when marked muscular atrophy is present. In fact, it should be emphasized that the old fashioned term "rheumatism" (including as it should myositis, arthritis and neuritis) is a much better term than "arthritis," just because it is inclusive. Moreover, "rheumatism" is a disease treated by general practitioners, and "arthritis" tends to drift to orthopedic specialists.

The list of infections that may be associated with polyneuritis is long. In several of those listed (table 1) subacute abscess formation is probably a factor. In a number of them dietary deficiency undoubtedly plays

11. Copeman, W. S. C.: The Treatment of Rheumatism in General Practice, Baltimore, William Wood & Co., 1933.

to light and well in accommodation. The hands and feet were cold, dry and desquamating.

Laboratory Data: The urine was normal. Examination of the blood showed hemoglobin, 50 per cent; red blood cells, 3,850,000; white blood cells, 5,400; differential: 60 per cent polymorphonuclears, 28 per cent lymphocytes, 4 per cent monocytes, 2 per cent eosinophils and 6 per cent basophils. The smear showed achromic red cells with normal size and shape. The Kalin test was negative. Lumbar puncture showed an initial pressure of 130 mg. of water, good dynamics; it was clear with no cells; the protein was 47 mg. per hundred cubic centimeters; colloidal gold test, 0012110000; the Kahn test negative. Gastric analysis: There was no free hydrochloric acid fasting, thirty minutes following 40 cc. of 7 per cent alcohol or thirty minutes following 1 mg. of histamine subcutaneously. Combined acid was 0.3, 0.5 and 0.6 per cent, respectively.

If this patient had fabricated lies to compensate for his memory defect—in other words, if he had shown typical “confabulations”—the case would have been labeled “Korsakow’s psychosis” and the pellagrous aspect of the disease might have been largely overlooked. Since this special sort of memory defect was not found (probably because he was too dull and confused to make an effort to fill in the memory gaps), the case was diagnosed “pellagrous psychosis.” On such tenuous threads do differential diagnoses hang! An understanding of the pathologic process causing these two supposedly separate syndromes makes it obvious that no differential diagnosis is necessary, for they are merely slight variations of one and the same disease process. In a recent paper on alcoholic polyneuritis¹² one of us emphasizes how unsatisfactorily the pathology has been studied but shows that, when viewed from the new standpoint of deficiency disease, some order seems to rise out of the chaos. The patho-

spicuous lesion. A third, less observed or rarer, has spinal cord lesions resembling those found in pernicious anemia. Scurvy, too, may result from chronic alcoholism and an analogy might be drawn between the vascular lesions of scurvy and those found in “polio-encephalitis superior” due to chronic alcoholism.

Fig. 4.—The black areas show the location of hypesthesia for pin prick, temperature and light touch on June 27, 1933. Pressure on the soles and muscles of the legs and thighs, however, causes sharp shooting pain. Vibration and position sense are absent at ankles and wrists.

Fig. 3.—Black areas on hands and feet show location of hypesthesia for pain, temperature and light touch on Dec. 16, 1932.

logic changes of one group of alcoholic patients closely resemble those of beriberi, in which the lesions are essentially a degenerative neuritis of the long peripheral nerves. Another group, the Korsakow syndrome, has pathologic changes much like pellagra, in which nerve cell degeneration in the cerebral cortex is the con-

Thus it is evident that the old narrow classifications must be broken down; many cases will not exactly fit the diagnosis of “pellagra,” “beriberi” or “alcoholic neuritis,” and cases of dietary deficiency are known to show all these lesions—cerebral, spinal and neural. Even clinically the classification is less dogmatic. For instance, “alcoholic pellagra” and “alcoholic beriberi” are becoming accepted diagnoses. It is not a question of fine differentiation of syndromes but a problem of broad understanding of the pathologic process, which is alike in all but variously localized. This localization of the process in different parts of the nervous system determines quite different symptoms. In other words, the imbibing of alcohol may, by its effect on the digestive tract and the diet, precipitate neuronal degeneration (and perhaps vascular lesions) in the brain, cord or peripheral nerves. If the process is largely in the brain and peripheral nerves, Korsakow’s syndrome results. If the brain is affected severely, with less degeneration of the cord and least in the peripheral nerves, the syndrome is that of pellagra. The converse of this picture is “alcoholic” polyneuritis, while Nonne’s “myelitis intrafunicularis” is intermediate between these two.

Such a classification may be too schematic, but it gives a point of departure to the clinical investigator and a chance to rearrange the facts of this group of diseases. If the cases observed in the next few years fit fairly well into this classification, the value of having had the temerity to make such a speculation on inadequate data will have been proved.

The importance of recognizing that these lesions are due to definite dietary restriction and not to alcohol per se or any vague “toxin” is of great practical importance. In the first place, patients should be immediately

12. Minot, G. R.; Strauss, M. B., and Cobb, Stanley: New England M. J. 208:1244 (June 15) 1933.

and actively treated with concentrated vitamins, by mouth and parenterally. Secondly, state aid to the needy must be scientifically given; soup kitchens and bread lines can induce severe nervous and mental diseases if unbalanced diets are given out. The expense of giving adequate vitamins is small; the cost of feeding many people on an inadequate diet is great in future suffering and institutional care. Pellagra is not a rare disease. In large city hospitals many cases are found, especially among the aged and destitute. These old folk frequently live in rooms or attics, cook a little for themselves over a gas burner and go out occasionally for a meal. Their diet is inadequate at best. If alcohol is used to drown boredom or despair, appetite is reduced and even less is eaten. Neuritis, pellagra or subacute degeneration of the spinal cord eventually results; sometimes two or even all three of these conditions occur. Anemia and dermatitis are concomitants. Just how the blood changes, the skin lesions and the neuropathologic changes are related is not yet known; it used to be thought that "pernicious anemia" caused "combined system disease." This is now known to be untrue. Some common cause is working to start the two abnormal processes. The paresthesias of early pernicious anemia are probably due to slight neuritis; in the later stages of the disease, polyneuropathy with excruciating tenderness may dominate the symptom picture. Some types of beriberi and of alcoholic neuritis are indistinguishable; in fact, one might call the latter "white man's beriberi," a disease due to the substitution of alcoholic calories for food.

CASE 4.—Neuritis due to lead poisoning. A white man, aged 50, admitted to the Neurological Service of the Boston City Hospital, Aug. 20, 1931, complained of weakness of the arms and legs of ten days' duration. His illness dated to four or five months before, when there was considerable gastric distress without vomiting. One month before entry he noticed that his arms and legs were weak and became easily tired. The arms became increasingly weaker until he was unable to lift ordinary objects. Finally he could not lift his knife and fork to eat, or even button his clothes and care for himself. He noticed that his hands were cold and his right shoulder was "sore." During the five months of illness he had lost 20 pounds (9 Kg.) in spite of the fact that he was on a fairly good diet.

For the past seven years he had used a moderate amount of whisky; careful questioning showed that recently it had been "home brew" distilled in an improvised apparatus, the "worm" of which was a long coil of lead pipe. On test a sample of this brew showed 2 mg. of lead per liter.

On physical examination the patient was poorly nourished and extremely emaciated; he was lying in bed and was unable to raise his arms. The abnormalities noted included peripheral arteriosclerosis, beginning bilateral opacities of the lenses, carious teeth, pyorrhea, typical lead line on the gums, emphysematous chest, palpable liver, and varicosities of the legs. The blood pressure was 130 systolic, 75 diastolic.

On neurologic examination the patient was euphoric but well oriented, with good memory and normal sensorium. The cranial nerves showed no involvement. There was a very marked generalized wasting of the muscles of the trunk and extremities. This was more noticeable in the forearms than in the arms, and more noticeable in the legs than in the thighs. It was most conspicuous in the small muscles of the hands. The muscles were very irritable and contracted in localized spasms when stimulated by tapping. The shoulder girdle and abdomen showed weakness and atrophy. Fibrillary twitches were seen in the leg and arm muscles after exercise. There was bilateral complete wrist drop and partial foot drop. The patient walked with difficulty. He could not raise his arms to the level of the clavicles because of weakness at the shoulder and elbow. The hand grip was weak, flexion of the wrist was weak and extension of the wrist was absent. All types of

sensation were normal except for diminution of vibratory sense of the right leg. The knee jerks were weak; the ankle jerks were absent; the tendon reflexes at the wrists and in the biceps of both arms were absent; the triceps jerks were weak. The abdominal reflexes were easily fatigued; the cremasteric reflexes were absent. The sympathetic system was normal except for slightly irregular pupils, which reacted sluggishly to light and in accommodation. The hands were cold and sweaty.

Urinalysis was normal except for an occasional white blood cell. Examination of the blood, September 8, showed hemoglobin, 55 per cent (Sahli); red blood cells, 3,090,000; white blood cells, 5,000; differential: 69 per cent polymorphonuclears, 26 per cent lymphocytes, 2 per cent eosinophils and 2 per cent monocytes. There were anisocytosis, poikilocytosis, achromia, and twelve stippled cells per high power field. The platelets were normal. The blood Wassermann and Hinton tests were negative.

Gastric analysis showed absence of free hydrochloric acid in the fasting sample; acid was also absent thirty minutes after 50 cc. of 7 per cent alcohol, and after 1 mg. of histamine intramuscularly. Lumbar puncture, August 21, showed an initial pressure of 75 mm. of water; 2,360 red blood cells; 52 mg. of protein per hundred cubic centimeters; colloidal gold test, 0011000000, and a negative Wassermann reaction. Roentgenograms showed a lead line in the epiphyses of both femurs. A recent sample of the whisky that he had been using for seven years showed 2 mm. of lead per liter. Biopsy of the gum showed microscopic deposits of lead sulphide.

The patient was given a diet rich in vitamins and calcium. At intervals, acidosis was induced with ammonium chloride. Iron ammonium citrate was given for the secondary anemia. The blood gradually approached normal over a period of five months, there being less variation in the size and shape, and less stippling of the red cells. During four months of this gradual deleating process he showed slow muscular improvement. By Jan. 2, 1932, he was able to raise his arms above his head. The shoulders, arms and grip of the hands were much stronger. The extensor muscles of the hands were still weak, especially the right. Ammonium chloride was prescribed and he was sent to the outpatient department. His condition continued to improve. In September he could make all movements normally, but his grip was still weak and he could not extend his wrists or raise his arms against strong pressure. Atrophy of the muscles of the hands, arms and shoulder girdle was still obvious. In January 1933 the muscles were apparently normal, although the patient stated that they were much smaller than before his illness. The only obvious abnormality was the loss of deep reflexes, the biceps, radial and ankle jerks being still entirely absent; the knee jerks were present but weak.

Lead as a poison to the nervous system has been known for centuries, but its effect on muscles, its storage in bones, and the deleating treatment by acidosis are modern advances of importance.¹³ Like all substances injurious to the nervous system (viruses, bacterial toxins, metabolic toxins, and drugs), different forms of lead seem to attack different parts of the nervous system. Metallic lead and the oxides have a predilection in adults for the more distal muscles and nerves of the extremities, whereas tetra-ethyl lead (used in gasoline) attacks the cerebral cortex. In children the lead in paint almost invariably causes an encephalitis rather than a neuritis. What causes these specific vulnerabilities of certain tissues to certain poisons is unknown. Much has been written on the subject, especially by Oskar Vogt,¹⁴ who calls the local susceptibility of certain parts of the nervous system to certain poisons "pathoklisis" and believes that it is due to "chemical affinity." Whatever the cause, it is a most remarkable phenomenon, and conspicuous examples are common: methyl alcohol especially affects the optic

14. Vogt, Oskar: *J. f. Psychol. u. Neurol.* 31: 245 (June) 1925; *abstr. Arch. Neurol. & Psychiat.* 15: 262 (Feb.) 1926.

nerve; the triorthocresol phosphate of "jake" paralysis¹⁵ and the "patent medicine" named "Apiol"¹⁶ affect almost exclusively the peripheral motor nerves; carbon bisulphide¹⁷ chooses the sensory nerves of the hands and feet, while trichlorethylene¹⁸ picks out the sensory part of the trigeminal nerve.

The list of metals, chemicals and chemical compounds that cause neuritis is long. In table 1 the best known are listed, but the list grows longer as industry advances and exposes its victims to new hazards. It was the airplane industry (stimulated by war) which in 1915 led to the discovery that trichlorethylene caused a sensory paralysis of the trigeminal nerve. Oppenheim¹⁹ was called to see these workers, who were putting a liquid "dope" on airplane wings indoors. His interest was aroused not so much because of the strange new disease but because he instantly saw that the discovery could be turned to good by numbing the agonies in trigeminal neuralgia; it has since been amply proved that he was correct in his theory.

Medicines (patented and otherwise) cause their share of neuritis. Arsenic in the form of sodium cacodylate was formerly given in huge doses to relieve the muscular rigidity in Parkinson's disease;²⁰ it worked, but by the obviously undesirable means of causing a peripheral neuritis and thus cutting off the impulses from the central nervous system to the muscle. Mercury and silver rarely cause neuritic symptoms, perhaps because other obvious symptoms appear earlier. More insidious may be the effects of chloral, chlorbutanol, barbitol, sulphonmethane and sulphonethylmethane. Worst of all was the devastation produced among the tipplers of the eastern and southern parts of the United States in 1930 by contaminating "jamaica ginger" with triorthocresyl phosphate.²¹ Literally hundreds of men and women were given an incapacitating drop foot, many of them permanently. Just as bad, if less extensive, is the poisoning recently caused in Europe by the same substance in a popular "patent medicine" called "Apiol," used to bring on menstruation and abort early pregnancy. This poison (like certain viruses) affects the peripheral axon most, but with sufficient dosage the ventral horn cell is also injured and sometimes destroyed; this causes a permanent paralysis—a chemical "anterior poliomyelopathy."

It has long been held that ethyl alcohol caused polyneuritis. The usual conception was that the alcohol itself acted as a direct toxin on the axon and cell body of the nerve. The evidence for this is scanty; little experimental work²² has been done which is not open to the criticism that the alcohol given not only acted as a toxin but also as a food, thus restricting the animal's intake of necessary vitamins. In human cases of alcoholic neuritis it is obvious that the imbibing of alcoholic beverages restricts the patient's diet and that neuritis apparently supervenes only after a prolonged dietary deficiency. This point of view has recently been put forward by Minot, Strauss and Cobb,¹² who have studied, during the last five years, a large group

of cases with the dietary etiology in mind. They conclude that a lack of vitamin B is the probable cause of the neuritis. Moreover, two investigators²³ have tried the crucial experiment of treating cases of alcoholic neuritis and pellagra with large amounts of vitamin B during periods when the patient was still drinking large quantities of alcohol; marked improvement took place in spite of the ingestion of alcohol. It is obvious that alcohol is a toxin, but it may not be a neuritic poison to a man in good health. The situation is not a simple one. If ethyl alcohol per se caused neuritis, the disease ought to be even more common than it is. It may be that alcohol causes neuritis only in people already debilitated by inadequate diet and infection. To us it seems more probable that the alcohol acts only by restricting diet and that this restriction causes beriberi.

Another factor worthy of investigation in all cases of alcoholic neuritis is the possibility of impurities in the liquor imbibed. The great English epidemic of arsenic poisoning from beer²⁴ was at first looked on as alcoholic. More recently arsenic has been found in the urine of many patients with neuritis attributed to alcohol.²⁵ Lead also is a common contaminant of alcohol, as in the case just reported. Some investigators hold that it is not the alcohol but the contaminants that cause neuritis.

LOCAL NEURITIS

We have said that the polyneuritides with their systemic toxins and generalized symptoms were medically more important than the localized neuritides. This is certainly true as far as risk to life is concerned, but when one considers the great number of patients complaining of local neuritis seen in outpatient departments and private practice, one must admit that local neuritis is an important problem. Surgically it is of great interest because many cases of trauma to nerves need operation, tumors that press on nerves have to be removed, and orthopedic cases presenting abnormalities such as cervical ribs pressing on nerves, arthritic exostosis and fibrosis form a large group. Some of these are severe and painful; others cause only an incidental annoyance.

Edema in a nerve trunk may interrupt passage of the nerve impulses along the axons, especially if the edema happens to be at a point at which the nerve is passing through a bony canal. A common case in point is that of a facial nerve which leaves the skull through the stylomastoid foramen. Exposure of the face to severe cold, a strong wind or local cooling (as in driving a closed automobile with only one window open, so that the wind blows directly on the cheek) often brings on edema that blocks the foramen, presses on the facial nerve and causes paralysis, so-called Bell's palsy. Local infection may have the same result.

Fibrosis about nerves may cause pain, paresthesia or paralysis. One of the common localities where this may take place is along the external cutaneous nerve of the leg as it passes through a fibrous tunnel in the fascia lata. This local fibrosis causes the syndrome known as "meralgia paraesthetica."²⁶ Infection in wounds, as in military surgery, often leads to fibrosis

about nerves with varying symptoms;²⁷ when the sympathetic nerves are involved in this way, a painful syndrome may result with vasomotor and trophic disturbances in the affected limb. This was described by Weir Mitchell in the Civil War and given the name "causalgia."²⁸ Fibrosis about joints may explain the striking but rare picture of neuritic pain with marked muscular atrophy sometimes seen in the distal portion of a limb when the proximal joints are rheumatic. The arthritis may not be especially conspicuous, and the muscular atrophy may be striking and rapid.

Local neuritis due to infection or bacterial toxin is uncommon except in diphtheria. In this disease the nerves near the seat of infection are frequently affected locally, causing palatal paralysis when the infection is faucial; other cranial nerves may be paralyzed and, of course, general polyneuritis is not rare. The most striking cases are those described by Walshe,²⁹ who saw wounds of the limbs infected with the diphtheria bacillus and local ascending neuritis in the contiguous nerves. Tetanus may act in much the same way, and even tetanus antitoxin when given repeatedly into one limb occasionally causes a local motor paralysis.³⁰

We have seen one case in which repeated intravenous injections of gas bacillus antitoxin into one arm caused local motor paralysis of the biceps, triceps and shoulder muscles of that side. Reports of local neuritis following vaccination with cowpox are occasionally heard; these lesions, however, may be due to pyogenic organisms and not to the virus.

A rare but virulent form of neuritis may arise from streptococcal infection in wounds.³¹ More chronic forms arise from infected bed sores in debilitated patients. Leprosy is the disease that gives the most obvious pathologic picture of a true local ascending neuritis; here the process is slow and the organisms may be easily identified under the microscope in the thickened nerve trunks.

Tuberculosis is usually mentioned as a cause of neuritis. Of course, tuberculous exudate or tubercle may act as a tumor and cause local pressure on nerves or even local invasion of nerve sheaths, but "tuberculous neuritis" is more a pathologic curiosity than it is a disease entity. Likewise, syphilis is always discussed in textbooks as a cause of neuritis. Myelitis affecting ventral horn cells and meningitis affecting nerve roots as they leave the cord are common in syphilis. Naturally they result in paralysis, muscular atrophy and other symptoms seen also in neuritis. True peripheral neuritis, however, due to syphilis we have never seen. The neuritis seen in terminal states of tuberculosis and syphilis is probably due to the cachexia and not to the infectious organisms.

SUMMARY

1. *The Polyneuritides That May be Caused by Virus Infection.*—The group of diseases caused by viruses is becoming rapidly larger as the problem is better understood, but our knowledge is still rudimentary in this field. Many of these diseases may be accompanied by peripheral neuritis, usually as a late complication; but when the virus attacks the spinal cord and nerves primarily the opposite is true. For example, the tenderness of the muscles in the early stages of acute anterior

poliomyelitis is probably due to the beginning of degeneration of the neuron including the axon; thus, pathologically speaking, there is a neuritis. The acute infectious or acute febrile type of polyneuritis, illustrated by case 1, is becoming a well recognized entity. There is evidence that this is due to a virus, probably specific, but as yet unknown.

2. *The Polyneuritides That May be Caused by Absorption of Bacterial Toxins.*—A long list may be made of infectious diseases known to be complicated by polyneuritis. The obvious inference is that absorption of the toxins formed by the invading organism causes the neuritis. The reasoning, however, does not hold, for neuritis is usually a rare complication of these diseases, and other factors must be evoked in order to explain the occurrence. Of course the neuritis following "serum sickness" is the best evidence available that bacterial toxins cause neuritis. In typhoid and other prolonged fevers, vitamin deficiency must be considered as a possible etiology. In diseases that may be due to pyogenic organisms (e. g., the first ten on the list under bacteriotoxic, table 1), the neuritis rarely develops early in the course of the illness. Generally it is late, when the infection has become chronic, and then abscess formation with absorption from a chronic focus must be looked for and treated. The second case reported here is in point. A chronic neuritis, especially if accompanied by arthritis and myositis, may well be due to focal infection of this sort; infections of tonsils, teeth or gallbladder may be implicated. The term "rheumatism" is used to include all these, and it is emphasized that a mild neuritis is often overlooked when it occurs with a conspicuous arthritis. Not infrequently acute infection acts as a precipitating factor in neuritis owing to deficiency of vitamins; especially in children the acidosis resulting from fever may determine the onset of lead paralysis.

3. *The Polyneuritides That May be Caused by Vitamin Deficiency or Metabolic Disorder.*—Good evidence is fast accumulating to indicate that the many polyneuritic syndromes listed in table 1 under "deficiency in metabolism" are merely clinical variations of one etiologic group. The first thirteen on the list, at least, seem to be caused by deficiency in one or more vitamins. The neuritis of diabetes may perhaps be caused or precipitated by the dietary restrictions imposed on the patient. Little is known of the syndromes known as "recurrent" and "chronic progressive neuritis," but the descriptions suggest an etiology based on vitamin deficiency. The neuritides associated with myxedema and hematuria apparently have a metabolic origin, but using that term thus vaguely really explains little. All one can say is that knowledge is now advancing rapidly in this field; the isolated discoveries at first seem to complicate the picture; soon etiologic relationships will be clearer, and then the long list of clinical syndromes here set down may be reduced to a few recognizable diseases.

4. *The Polyneuritides That May be Caused by Chemical Substances Ingested.*—The neuritis caused by lead and by arsenic is well known. Modern industry has increased the hazards to which workers are exposed, and a list of eighteen substances is given in table 1 that are said to cause polyneuritis. The extraordinary specificity of some of these substances is emphasized; certain of them always appear to attack one special pair or group of nerves. It is argued that ethyl alcohol is not a neuritic poison but, when taken as a beverage,

either causes dietary deficiency and hence beriberi or causes neuritis because of impurities. A case is given of lead poisoning due to impure alcohol.

5. *The Local Neuritides Caused by Pressure and Trauma.*—These are largely surgical problems. Local edema and fibrosis are common etiologic factors often overlooked.

6. *The Local Neuritides Caused by Infectious Organisms and Their Toxins.*—These are rare except in the case of diphtheria.

Clinical Notes, Suggestions and New Instruments

SUCCESSFUL SUTURE OF A WOUND OF THE ASCENDING AORTA

ALFRED BLALOCK, M.D., NASHVILLE, TENN.

There has appeared in the literature only one report of the successful suture of a wound of the thoracic aorta. This operation was performed by Dshanelidze¹ of Russia. The reasons for the scarcity of successful cases are several. For purposes of this discussion, the aorta is divided into two portions; namely, that part which is within the pericardium and that which is without. Piercing injuries of the extrapericardial portion of the thoracic aorta usually result in early death

of the intrapericardial part of the aorta is due to its position behind the sternum and to the fact that it is quite short.

I have noted in studies on animals that relatively small wounds of the intrapericardial portion of the aorta are usually fatal unless treatment is instituted. A wound of the aorta 3 mm. in length usually causes death, while a similar opening in the intrapericardial part of the pulmonary artery does not. Wounds of twice this length of the left or right ventricular walls rarely cause death in the experimental animal.

Fig. 2—Appearance of the patient following the healing of the incision.

Fig. 1—Incision used for the exposure of the heart and the wound of the aorta. A clamp was used for pulling the right auricular appendix to the right.

because there is no surrounding structure such as the pericardium to limit the loss of blood. The infrequency of wounds

of the intrapericardial portion of the ascending aorta of a Negro youth

A Negro, aged 18, entered the Vanderbilt University Hospital, Sept. 17, 1932, approximately forty-five minutes after having been stabbed in the chest and neck with an ice pick. He was extremely restless, the respirations were labored, the skin was cold and clammy, the radial pulse could not be counted with accuracy, and the blood pressure was 50 mm. of mercury systolic and 40 mm. diastolic. There was a small wound immediately to the left of the sternum between the first and second ribs. There was no bleeding from this wound. The heart sounds were heard over the base with difficulty. The veins of the neck were quite distended. There was a small wound of the lower part of the neck on the left side.

A 7 foot plate of the chest was made shortly after the patient entered the hospital. This showed a partial pneumothorax of the right pleural cavity and a small amount of fluid in the left costophrenic angle. The shadow of the heart and pericardium was thought to be a little larger than normal.

The patient was then taken to the operating room and 500 cc. of physiologic solution of sodium chloride was introduced intravenously while preparation for the operation was being made. A reading of the blood pressure could not be obtained before or immediately after the injection of the salt solution.

Nitrous oxide and oxygen was used as the anesthetic. A left parasternal incision with its center over the third costal margin was used for the approach. The attachment of a large part of the pectoralis major muscle was divided. The second and third costal cartilages together with parts of their ribs were removed. The internal mammary artery and vein were doubly ligated and divided. By the use of a pair of rongeurs, a part of the sternum was removed. The pleura was reflected laterally on each side and the pericardium was exposed. Several

attempts were made to grasp the pericardium with forceps, but these were unsuccessful, as it was quite tense. An incision was made into the pericardium and blood under pressure escaped. The quantity that was lost was estimated as 300 cc. As soon as the pericardium was opened, the blood pressure rose to 100 mm. of mercury systolic and 60 mm. diastolic. After the blood was sponged out from the pericardium it was observed that blood continued to accumulate in the region of the base of the heart. While this area was being sponged, a clot that was partially occluding an opening in the aorta was dislodged and a large stream of bright red blood shot over the screen at the head of the table on the anesthetist. The bleeding was controlled temporarily by digital compression. The right auricular appendage prevented a satisfactory view of the bleeding point, and a clamp was placed on the tip of the appendage in order that it might be held out of the way (fig. 1). The wound in the aorta was then closed with interrupted silk sutures. The first two sutures did not stop the bleeding. Traction was then made on these two sutures and a third one was placed between them. The wound was observed for several minutes and no further bleeding was seen. It was estimated that approximately 700 cc. of blood was lost during the procedure of suturing the opening in the aorta. The incision in the pericardium was closed with interrupted sutures. A small opening in the pleura, which had been made most likely by the ice pick, was closed, and the incision was then sutured tightly without drainage. The patient seemed to be in good condition at the completion of the operation. The pulse rate was 120 per minute, the systolic blood pressure 95 mm. of mercury and the diastolic 50 mm. A transfusion of blood was given shortly afterward.

There was an elevation of the temperature, pulse and respiration rate for several days following the operation. The patient complained of rather severe pain in the right side of the chest on several occasions. The incision healed by first intention without drainage and without having to be aspirated (fig. 2). He was discharged from the hospital, Oct. 25, 1932, and has remained well since that time.

A RAPID METHOD FOR THE DETERMINATION OF BLOOD EOSINOPHILIA

TOWNSEND B. FRIEDMAN, M.D., CHICAGO

In the diagnosis and study of the various allergic states it is frequently desirable to know the blood picture, especially the eosinophil count. The ordinary smear method, in which 200 or more cells are counted, is a time-consuming process and the chance for an error in the eosinophil count is great. Moreover, the result gives only the percentage of eosinophils in the number of cells counted. The method described here gives the number of eosinophils per unit volume of blood, is rapid and at the same time gives the leukocyte count.

Blood is collected in the usual manner for the blood count, accurately calibrated white cell pipets being used. In place of the usual acetic acid diluting fluid the following fluid, which is the modification of Camara and Alvarez¹ of that described by von Domarus,² is employed:

Aqueous eosin 1 per cent.....	5 cc.
Acetone	5 cc.
Distilled water	100 cc.

The count is made in the usual manner in the ordinary counting chamber. This diluting fluid stains only the eosinophilic cells and they are easily distinguishable with the high dry power of the microscope. The unstained leukocytes appear as gray bodies in this diluting fluid.

It is advisable to fill also a pipet with the ordinary acetic acid diluting fluid and use this count as a check until one has had some experience with the fluid described.

With this method I have found it very simple to follow the blood eosinophilia in asthmatic patients in their free period and during the acute attack.

PORCELAIN FAUCET HANDLE INJURIES

HAROLD P. MALONEY, M.D., OAKLAND, CALIF.

The porcelain faucet handle as a common household hazard has received too scanty attention. Not only are the injuries incurred painful and dangerous, but the resulting disabilities are often prolonged because of the frequency of nerve and tendon damage. The matter has not been entirely neglected, but, probably owing to the manner in which papers have been titled, search of the recent literature has not yielded any information of like character.

Over a period of four years about twenty cases have been seen in the office, in the emergency service of a private hospital and at the public health center. Five office cases are presented here in brief to illustrate the variety of injuries.

All the injuries were produced by one of the two types of china or porcelain handles illustrated (fig. 1). The porcelain is cemented with plaster of paris over a metal core or about a central metal hub. A certain variety of faucet has a metal core, continuous through the entire length of the porcelain. This type is relatively much less dangerous. A sharp blow of the hand against one of the first two handles mentioned can readily shatter the porcelain. The neglected, leaking faucet calls forth most of these sharp blows.

The bare hand driven with force against these glasslike broken edges rarely escapes injury. All the injuries listed have

been palmar or on the fingers. They have been of the puncture wound type, the surface injury being minimal compared with the damage done to deeper structures (fig. 2).

REPORT OF CASES

CASE 1.—E. M., a white man, aged 31, doing general repair work, was disabled for two weeks when, while he was testing a newly installed faucet, the handle broke off in his hand as he closed the faucet. Examination revealed a slicing laceration, three-fourths inch long and one-half inch deep, in the palm of the left

Fig. 1.—Two types of china or porcelain handles.

hand. Porcelain particles were picked out and the wound was cleansed, iodized and closed with dermol sutures.

CASE 2.—E. G., a white woman, aged 24, a housewife, while washing dishes, reached for the water faucet. As she turned it off, the handle cracked. Examination revealed a laceration one-half inch long, running transversely just distal to the proximal interphalangeal joint on the palmar surface of the right fifth finger. She was unable to flex the distal phalanx. Exploration revealed the tendon of the flexor digitorum profundus severed, with its proximal end retracted into the tunnel formed by the sublimis. The wound was cleansed and iodized and the tendon repaired with black silk. The end result was poor flexion of the distal phalanx, probably because of adhesions. The period of disability was three weeks.

CASE 3.—L. L., a white woman, aged 22, a housemaid, while working about the house, cut her hand when a faucet handle cracked off as she turned off the water. Examination revealed a one-half inch transverse laceration in the palm of the left hand. She could not flex either interphalangeal joint of the index finger. Exploration under general anesthesia, with a tourniquet in place, showed severing of the tendons of the flexors digitorum profundus and sublimis to the index finger. The tendons were repaired separately with black silk. Active

motion was allowed in three weeks. There was 75 per cent normal motion in seven weeks. In eighteen weeks recovery was complete.

CASE 4.—G. A. M., a white woman, aged 48, a housewife, while working about the house broke off a porcelain faucet handle in her left hand. Examination revealed a $1\frac{1}{2}$ inch

Fig. 2.—Location of injuries.

ragged laceration, roughly paralleling the medial palmar border of the fifth finger. The medial phalangeal artery was severed. The wound was cleansed, iodized and loosely closed. The period of disability was ten days. When last seen the medial half of the finger tip was still numb, although the severed nerve was not identified at the time of the injury.

CASE 5.—E. R., a white man, aged about 35, a garageman, received his injury when impatiently trying to close a dripping faucet by giving one additional twist. A 1 inch laceration was incurred, which bled freely. The laceration was in the central lateral half of the palm and extended proximally into the thenar eminence. Exploration revealed that the superficial volar artery was severed, as well as the branches of the median nerve to the short muscles of the thumb and the cutaneous supply to the lateral border of the index finger. Repair was tedious. Partial disability existed in the hand for six months. Disturbances in sensation still persisted after eighteen months, although muscular function was excellent.

COMMENT

These cases are illustrative of the lacerations that may occur. A slight variation is that of a male patient (not under my personal care) who, while seated in the bath tub, attempted to close the faucet with his foot. He suffered a large, jagged laceration of the sole.

These accidents are rather frequent. The opportunities for them are present in almost every household. They are preventable by substituting brass or chrome plated handles for the common porcelain type. Plumbers are aware that the handles very frequently break, but they have not been impressed by seeing the gravity of some of the injuries that occur. A chrome plated replacement handle of standard type is available at the same price as the ordinary porcelain handle. Other varieties with more style are to be had at slightly greater prices. Plumbing supply men feel that they must give the public what it wants and that is most often the porcelain handle; yet each household in which an accident has occurred feels "that there ought to be a law against such handles."

SUMMARY

1. The common porcelain faucet handle is a frequent source of injury and prolonged disability.

2. The injuries are characterized by minimal skin wounds with the frequent involvement of nerves, tendons and other deep structures.

3. Such accidents are largely preventable by early repair of leaking faucets to eliminate unnecessary force in closing, or fully preventable by substituting equivalent priced chrome plated handles for the porcelain ones.

4. Plumbers and plumbing supply men are aware of the hazard but answer that they must give the buyer what he wants.

5. Elimination of the hazard can be hastened by better informing the purchasing public.

411 Thirtieth Street.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY OF THE AMERICAN MEDICAL ASSOCIATION HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS.
H. A. CARTER, Secretary.

BURDICK ELECTROSURGICAL UNIT ACCEPTABLE

The Burdick Corporation, Milton, Wis., manufactures an electrosurgical diathermy unit, Model No. SU-2, which differs from other electrosurgical units, since it makes use of two currents—one from a spark gap high frequency generator and the other from a tube oscillating unit. The two currents may be blended or used separately, depending on the will of the operator.

The spark circuit is of the standard type with a well built mica condenser across the transformer secondary. The three spark gaps are satisfactorily designed and readily removed for adjustment or repair.

The tube circuit is of the well known and efficient Hartley, parallel feed plate, using "raw" alternating current for its anode voltage. It is isolated from the spark circuit by means of two condensers, one of which is a rotary variable air condenser.

Two taps (high and low "dissection intensity") are provided on the primary of the plate transformer to give different plate voltages and hence different power output from the tube. The filament of the FP 1 tube is connected directly across the 110 volt terminals when the main switch is on and continues to operate at all times whether the foot switches are used or not.

The blending circuit contains a coil, common to both spark and tube oscillators, from which leads for coagulation or dissection are brought out. A third foot switch, not shown in the diagram, turns on both sparks and tube oscillator simultaneously. The two units operate without influence on each other to any marked extent and hence the output blended current is the sum of their individual outputs.

All parts are rigidly mounted and the vulnerable tube and spark gap are readily accessible for replacement or repair. There appears to be sufficient ventilation to prevent overheating. A small and hence portable unit has been achieved by crowding the parts together. The electrical insulation is considered satisfactory. Sufficient and convenient control of the outputs has been provided. The table for carrying the instrument has reasonably large wheels, so that it rolls smoothly and easily.

Fig. 1 — Burdick electrosurgical diathermy unit, Model No. SU-2.

Temperature runs have been made by the usual resistance method on the plate transformer (a rise of 14 degrees C in two hours) and the spark transformer (a rise of 25 degrees C in one hour and twenty minutes) with a heavy load in use. These temperature rises appear to be within the limits.

The tube oscillator operates at 95 meters wavelength.

The spark coagulator operates around 725 meters wavelength and contains a third harmonic whose amplitude is approximately one-fourth that of the fundamental. In one instance (only) the wavelength was altered to 900 meters. The condition was that of a heavy load when the maximum voltage (tap switch No. 6) was in use.

Except for size, length of tube or shape, the burners for these lamps are essentially the same. The burners consist of a quartz-tubing about 7 mm. in diameter, which is highly evacuated of air and supplanted with an atmosphere of rare gases, xenon, krypton and argon, and a few drops of mercury. An electrical charge, taking place between the sealed-in electrodes, causes the lamp to glow, thus producing a light characteristic of a low pressure mercury vapor lamp.

In a physical laboratory acceptable to the Council, radiation tests indicated that more than 95 per cent of the total erythrogenic rays (of wavelengths 3,130 angstrom units, short waves) are emitted by the 2,537 Å line. By means of the filter method, it was found that 97.8 per cent of the erythrogenic rays are contained in the strong emission line 2,537 angstrom units.

The Fischerquartz Ultraviolet Lamps are included in the Council's list of accepted devices for one year.

COLD QUARTZ ULTRAVIOLET GENERATORS REACCEPTED

The Electro Therapy Products Corporation, Los Angeles, manufactures the Cold Quartz Ultraviolet Generator. The following models have been considered:

Junior, Mobile, Body Lamp (B-8)
Junior, Mobile, Combination Lamp (C-8)
Junior, Mobile Stand Official (S-8)
Junior, Portable Combination (PC-8)
Senior, Mobile, Body Lamp (B-7B)
Senior, Mobile, Combination Lamp (C-7B)
Senior, Mobile, Stand Official (S-7B)
Senior, Portable, Official (P-7B)
Standard, Mobile, Combination (C-7)
Standard, Mobile, Body Lamp (B-7)
Standard, Mobile, Stand Official (S-7)
Standard, Portable Official (P-7)
DeLuxe, Combination (C-710)

The Council on Physical Therapy declares these lamps reaccepted for a period of three years.

STRETCH-A-WAY REDUCER AND HEALTH EXERCISER NOT ACCEPTABLE

The Stretch-A-Way Company, 4500 Magnolia Avenue, Chicago, manufactures a device known as the Stretch-A-Way Reducer and Health Exerciser. This product may be described as a pair of leather stirrups supported on a wooden cross-bar, and a handle, jointed by a heavy cord of live rubber, which furnishes the tension for the exercises. A strap is provided to fasten the device into the floor or under a door. The method used in exercising consists of pulling against the tension of the rubber.

The firm asserts that the outfit is used for reducing excess flesh and bases the claims on the improvement in blood circulation and the toning and strengthening of the body muscles, especially those of the abdomen. Advantage is taken of the massage effect through rolling on the stretched muscles. Strengthening of sagging muscles, reducing hips and thighs, and improvement of posture are further claimed. The company advises the patient moderation in eating. The company goes on to say that the device makes regular exercise interesting, convenient and practical.

An advertising pamphlet used in the marketing program was examined and the Council declared the following statements misleading, since no conclusive evidence was submitted to substantiate these claims:

"Reducer and Health Exerciser—The modern way to health, beauty, and slenderness through rhythmic stretching exercises."

"Treating the metatarsal arches: Place feet in stirrups and pull up against the middle of the soles of the feet, with handle up to the waist. Curl the toes downward alternately, as far as possible. A beneficial deep massage is obtained."

"Endorsed by medical authorities." The firm failed to give the names of the medical authorities who have endorsed the method.

In view of the unwarranted claims appearing in the advertising matter, the Council did not include the Stretch-A-Way Reducer and Health Exerciser in its list of accepted devices for physical therapy.

The Chemical Laboratory

THE FOLLOWING IS A REPORT OF THE CHEMICAL LABORATORY OF THE AMERICAN MEDICAL ASSOCIATION. PAUL NICHOLAS LEECH, Director.

THE STERILOMETER AND THE ASEPTIC-THERMO INDICATOR

Sterilometers, manufactured by the Sterilometer Laboratories, of Los Angeles, and Aseptic-Thermo Indicators, manufactured by the Aseptic-Thermo-Indicator Co., also of Los Angeles, are products designed for determining effective sterilization of certain types of materials. The products are designed for inclusion in or near the center of packages of goods for pressure-steam sterilization to determine whether or not adequate sterilizing conditions have been met throughout the depth of the material. The A. M. A. Chemical Laboratory has received several inquiries as to whether or not the products meet the claims made for them.¹

The Sterilometer consists of a thermometer-like drawing on a piece of cardboard, the bulb and stem of which are of a light tan color. It is claimed that after a sufficient period of subjection to steam under pressure the column will match the bulb in a uniformly black color, and that this change takes place only after a period sufficient to insure complete sterilization (including destruction of spore-formers). The bulb is so constituted as to turn to black soon after exposure to heat, while the stem is the true indicator of sterilizing conditions. The Aseptic-Thermo Indicator is identical in principle and consists of a lavender arrow pointing to the figure 250° on a green dial.² Under conditions as outlined for the Sterilometer, the arrow matches the dial in color.

The two devices were called to the attention of the A. M. A. Chemical Laboratory by Dr. T. B. Magath of the Mayo Clinic, who had conducted a study of the Aseptic-Thermo Indicator. A small autoclave, susceptible of being heated to the desired temperature within thirty seconds and of being exhausted of steam and water in ten seconds, was constructed. The time and temperature recordings for this instrument were of established accuracy within limits, respectively, of ± 5 seconds and ± 0.5 C. With this apparatus, Indicators being selected at random, Dr. Magath obtained the results shown in table 1.

Twenty-five Indicators were used. After nineteen minutes the lavender color deepened to purple, yet Dr. Magath reported that the change to green did not occur until twenty minutes had elapsed, at which time all Indicator arrows matched their green dials. When the test was repeated at 126 C., the same condition obtained, except that the change occurred at sixteen and one-half minutes, again with all Indicators. In ascertaining the part played by moisture, twenty-five Indicators were submitted to dry, hot air at 170 C. for five hours. No change in color occurred. Because of a forty-second lag in the apparatus, the time recorded for color change to occur was considered as correct only within a possible error of ± 40 seconds (or a

TABLE 1.—Results Obtained with Aseptic-Thermo Indicators

Minutes	Steam at 15 pounds pressure	
	Temperature	Results
10	121 C.	No change in color
12	121 C.	No change in color
14	121 C.	No change in color
16	121 C.	No change in color
19	121 C.	No change in color
19.5	121 C.	No change in color
20	121 C.	Color change to green (matched)

maximum error of eighty seconds). Except for that relatively inconsequential source of error, the work appears to be critical,

1. In this consideration of the Sterilometer, and of the Aseptic Thermo-Indicator, the Dyack was not included because it belongs to that class of device whose reaction is largely dependent on temperature alone.

2. The reaction of these devices, according to their respective manufacturers are due (a) in the case of the Sterilometer to the formation of lead sulphide occurring at the melting point of a mixture of lead oxide, lead subcarbonate and sulphur; and (b) in the case of the Aseptic-Thermo-Indicator to an isomeric change of purple chromium sesquichloride to the green form.

precise and conclusive. The conclusion drawn is very broad and seemingly justifiably so:

These Indicators are satisfactory for testing sterilization with steam under pressure for all uses in bacteriologic laboratories and hospitals.

Under the auspices of the A. M. A. Chemical Laboratory, a further investigation of the products was undertaken. This was performed in the laboratory of, and in collaboration with, the department of bacteriology of a well known medical school.

8	40	186	No growth	No change	Complete change
9	45	184	No growth	No change	Complete change
10	50	185	No growth	No change	Complete change

The work was directed, roughly, toward investigating the various claims of the manufacturers as well as establishing a fair estimate of the reliability of the products.

The first experiment consisted in an investigation of the two products in autoclaves of two types (i. e., direct steam supply and gas-heated individual generators) and of various sizes. Conditions of temperature, pressure and duration of exposure were varied, as well, but constant for a given experiment. Twenty-three determinations were made, with the finding that no change in color of either the Indicators or the Sterilometers took place unless standard sterilizing conditions were met (20 pounds pressure of live, saturated steam for ten minutes of actual contact with the products). The variable, of course, is the time required for the penetration of steam into the packages being sterilized. In some instances, complete color change did not occur even though the so-called standard sterilizing conditions had obtained. This might be looked on as an additional margin of safety over and above the usual factor of safety in efficient sterilization.

The second experiment had to do with establishing whether or not complete color change indicated absolute destruction of all micro-organisms, including spore-formers. For this purpose one-centimeter squares of absorbent paper (Kleenex) were saturated with old broth cultures of *B. subtilis* or *B. welchii* and placed, one or the other, in sterile Petri dishes with a Sterilometer and an Indicator. At the conclusion of known periods of exposure to 15 pounds of pressure, the bacterial papers were removed with sterile forceps and deposited in favorable culture mediums. Control bacterial papers which were allowed to remain in sterile dishes at room temperature for as long as the duration of the longest autoclaving period were found to produce a good growth of both types of spore-former. The results are given in table 2. The conclusion, of course, is that a complete color change or "matching" of the indicators is evidence of complete sterilization.

Because of a statement that the "Sterilometer is so constructed that it changes color to black only in the presence of live steam," the next test was performed. Bacterial "squares" were again prepared, this time with *B. anthracis*, and employed as in the previous experiment except that, in this case, the dishes were placed in an oven for periods of from five to fifty minutes and with temperature varying from 168 C. to 185 C. The results are given in table 3. It is apparent that dry

heat has no effect on the Aseptic-Thermo Indicator but that the Sterilometer exhibits complete matching throughout, after thirty-five minutes. Apparently, therefore, the Sterilometer is an efficient indicator of sterilization by dry heat as well as by steam-pressure. The experiment does, of course, refute the claim that the Sterilometer assures the presence of live steam, although such is actually the case with the Indicators. Baking the two types in an oven at 180 C. for ninety minutes produced no change in the Indicators but an almost complete change in one of the three Sterilometers so tested. Immersion in boiling water for periods of ten, fifteen and twenty minutes produced partial color changes of the Sterilometers but not of the Indicators, while exposure to the open Bunsen flame for thirty seconds produced complete matching in the case of the Sterilometers and, again, no change of the Indicators.

Information concerning effects of light, age, and so on, was then sought by placing sets of four each of the two types in (a) an incubator at 37 C. and (b) a paraffin oven at 56 C. At weekly intervals one of each was removed and checked against an unused control for stability of color and retention of indicator efficiency. With the same technic used with anthrax cultures as before, the results shown in table 4 were obtained.

The test products were all submitted to three weeks of incubator or paraffin oven conditions before being used. Such treatment caused the Sterilometers to undergo incomplete color changes when subjected to efficient steam-pressure sterilizing conditions, as compared to controls. The Aseptic-Thermo Indicators were not affected. Sunlight produced bleaching of the Sterilometer.

SUMMARY

The foregoing indicates that either type of indicator, whether Sterilometer or Aseptic-Thermo Indicator, is efficient in determining sterilization by the autoclave. The Sterilometer appears to be equally efficient in determining sterilization by dry heat but it has the disadvantage, as compared with the Indicator, that it is rendered irregular in its action by artificial methods of aging and is subject to complete color change in the open Bunsen flame and partial color change in boiling water. Apparently, neither product could cause a false feeling of security since, whenever the reaction or change was irregular, matching did not occur. The error in every instance was on the side of safety and failure of matching. Whenever color change had proceeded to the point of matching, sterilizing conditions had been met sufficiently to result in the destruction of all micro-organisms, including spore-formers. Naturally it is

TABLE 4.—*Effects of Light and Age*

Pressure and Time	Temperature, C.	Culture	Effect on Indicators	
			Sterilometer	Aseptic-Thermo Indicator
Control	37	+		
Control	22	+		
20 lbs. 2 min.	127	—	Control, brown Incubator, brown Paraffin oven, brown bulb; too steep	Control, no change Paraffin oven, no change
20 lbs. 10 min.	127.5	—	Control, matched Incubator, matched Paraffin oven, brown bulb; not quite matched	Control not quite matched Paraffin oven, not quite matched
15 lbs. 5 min.	122	—	Remainder cannot be charted intelligently, since only one specimen of each was used and it is not stated whether such specimen is a control or one of the incubator or paraffin oven products; in no instance did the Indicators match; the Sterilometers matched in two, as noted by the asterisks	
10 lbs. 8 min.	118	—		
5 lbs. 25 min.	112	—

10 lbs. 30 min.	116.75	—		
5 lbs. 90 min.*	112.75	—		

understood that the water vapor in the autoclave does not contain appreciable amounts of hydrogen sulphide, the presence of which theoretically might vitiate the results, in the case of the sterilometer.

CONCLUSION

The Sterilometer and Aseptic-Thermo Indicator, if further studies are equally confirmatory, may be found of distinct value in hospitals and bacteriologic and pathologic laboratories.³

3. As with any automatic recording device, the human element plays an important part. For that reason it should be emphasized that these devices should be used with due regard for their location in surgical bundles, and for proper functioning of the autoclave itself.

Committee on Foods

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

RAYMOND HERTWIG, Secretary.

Description.—Bottled pasteurized milk fortified with vitamin D (vitamin D concentrate prepared from cod liver oil); contains 400 U. S. P. X (Revised, 1934) vitamin D units per quart.

Preparation.—The milk complies with legal requirements and is pasteurized by the standard holding method. See THE JOURNAL, July 1, 1933, page 34, for description of fortification with vitamin D.

Vitamins.—The vitamin D concentrate used and the fortified milk are regularly tested biologically. Clinical investigation shows this milk to be a reliable antirachitic agent, if the proper amount is used.

Claims of Distributors.—A vitamin D fortified, antirachitic pasteurized milk having otherwise the flavor and food values of usual pasteurized milk.

BORCHERDT'S MALT SOUP EXTRACT WITH ADDED POTASSIUM CARBONATE

Manufacturer.—Borchardt Malt Extract Company, Chicago.

Description.—Concentrated nondiastatic malt extract with added potassium carbonate.

Manufacture.—Crushed barley malt is admixed with warm water and stirred for a definite period; a given quantity of hot water is added and steam is introduced until the temperature of the mix rises to the desired point, at which it is held for a definite period, after which the water solution is removed from the grain, filtered, and partially evaporated. Potassium carbonate is added to this malt extract (1.1 Gm. of potassium carbonate to 100 Gm. of extract) and the mixture is further concentrated in "vacuum" to the desired density, and packed in bottles.

Analysis (submitted by manufacturer).—	per cent
Moisture	21.8
Ash	2.5
Potassium carbonate.....	1.1
Fat (ether extract).....	0.0
Protein (N X 6.25).....	6.4
Reducing sugars as maltose.....	57.6

Not diastically active.

Calories.—3.0 per gram; 85 per ounce.

Vitamins.—Sixty units of vitamin B complex (Sherman and Spohn method) per ounce.

Claims of Manufacturer.—A laxative modifier in the diet of obstinate cases of constipation in bottle fed babies. Is mixed with water, whole milk and wheat flour in certain proportions to make Keller's Malt Soup for special diets of infants.

SANKA COFFEE (97% OF THE CAFFEINE REMOVED)

Manufacturer.—Sanka Coffee Corporation, New York, subsidiary of General Foods Corporation, New York.

Description.—Decaffeinated Santos, Bogotas and Mocha coffees, retaining approximately 3 per cent of the natural caffeine.

Manufacture.—Green coffee is cleaned, steamed and the caffeine extracted with trichloroethylene, which is removed by steam distillation. The different coffees are blended to produce a standard coffee beverage, roasted and automatically packed under vacuum in tins. Every batch is tested to insure at least 97 per cent removal of caffeine.

Analysis (submitted by manufacturer).—	per cent
Moisture	3.1
Water soluble solids.....	24.5

SATURDAY, NOVEMBER 24, 1934

THE CONFERENCE ON ECONOMIC SECURITY

In his address to the National Conference on Economic Security, November 14, President Franklin D. Roosevelt made the following statement on the subject of old age pensions and sickness insurance:

I do not know whether this is the time for any federal legislation on old age security. Organizations promoting fantastic schemes have aroused hopes which cannot possibly be fulfilled. Through their activities they have increased the difficulties of getting sound legislation; but I hope that in time we may be able to provide security for the aged—a sound and uniform system which will provide true security.

There is also the problem of economic loss due to sickness—a very serious matter for many families with and without incomes and therefore an unfair burden upon the medical profession. Whether we come to this form of insurance soon or later on I am confident that we can devise a system which will enhance and not hinder the remarkable progress which has been made and is being made in the practice of the professions of medicine and surgery in the United States.

These words are to the medical profession, among the most encouraging to come from the conference. They recognize the fantastic character of many of the schemes that have been proposed for these types of economic security. They indicate also a realization of the necessity for developing changes in the nature of medical practice that will neither break down the quality of medical care nor impede medical progress.

The report of the deliberations of the Medical Advisory Board would seem to indicate a tendency on the part of the advisers to follow the lead of the President in prefacing action and recommendation by study and investigation.

In her statement to the National Conference on Economic Security, Miss Frances Perkins, Secretary of Labor, said:

Ill health is a hazard which may strike at any age and is rendered particularly distressing by the economic considerations that are involved. Through its Public Health Service the government has for a long time accepted a certain measure of responsibility for the health of the people. That service, by its preventive and educational work, has played an increasingly valuable part in improving the national standards of health. But we cannot shut our eyes to the fact that vast numbers of our people in time of sickness are unable to pay the cost of necessary medical attention.

From time immemorial the members of the medical profession have cared for the needy without thought of reward. They have consistently rendered this noble and unselfish service, but we cannot in fairness ask them to carry indefinitely a burden which under the stress of modern conditions becomes daily heavier. Our problem is to bring adequate medical care within the reach of those who cannot at present afford it, and at the same time to safeguard the highest interests of that profession which has always given without stint of its services to the care of suffering and needy humanity. To this end the cooperation of the medical profession is vital and I have every confidence that such cooperation will be accorded by the profession, which has always had such fine traditions of public service.

Miss Perkins in concluding her remarks emphasized the statement by the President that "we must not lose sight of the fact that economic recovery must come before everything else and that unemployment insurance, as well as the other parts of the economic security program, will have to be developed as a cooperative federal-state undertaking."

The Medical Advisory Board to the Committee on Economic Security held its meetings on November 15 and 16. A brief statement appears under Association News in this issue (p. 1627). There is apparent a desire to enlist the cooperation of the entire medical profession in the development of recommendations that will answer the desire of the social leaders for better provision of medical care to the lower income groups in our population and at the same time protect the advancement of scientific medicine, the quality of medical care and the private practice of medicine. It is no secret that all of the plans thus far brought forward involve tremendous expenditures of money, running into billions of dollars annually, and this too at a time when budget balancing is a problem to tax the most astute minds that the administration is able to command. An evidence of the tendency to proceed with due caution is the recommendation by the Medical Advisory Board¹ of the addition to the technical staff that is studying this problem of Dr. R. G. Leland and Mr. A. M. Simons of the Bureau of Medical Economics of the American Medical Association. The technical staff previously included Dr. Edward Sydenstricker and Messrs. I. S. Falk, Michael Davis and Nathan Sinai. It is understood that this technical staff will make the basic studies and fact-finding investigations that are necessary before the committee can proceed intelligently to formulate its final recommendations.

The headquarters office of the American Medical Association has been besieged with telephone calls, telegrams and letters on this subject ever since the plans for this conference were first made public. Some physicians are apparently opposed to all change and feel that the American Medical Association should officially make itself felt in opposition to the entire program of

1. The members of this board include: Dr. Harvey Cushing, New Haven, Conn.; Dr. Walter L. Bierring, Des Moines, Iowa; Dr. James Alexander Miller, New York; Dr. Robert B. Greenough, Boston; Dr. James D. Bruce, Ann Arbor, Mich.; Dr. Rexwald Brown, Santa Barbara, Calif.; Dr. Thomas Parran, Albany, N. Y.; Dr. George W. Crile, Cleveland; Dr. Stewart R. Roberts, Atlanta, Ga.; Dr. George M. Piersol, Philadelphia, and Dr. J. Shelton Horsley, Richmond, Va.

the government. While the House of Delegates of the American Medical Association has repeatedly voiced its opposition to the socialization of medical practice, it indicated, in its sessions at Cleveland last June, its belief in properly controlled experimentation with new forms of medical practice, subject to the retention of certain basic principles recommended by its own special committee. This is the policy which *THE JOURNAL* and the *Bulletin* of the Association have supported to their utmost.

It now remains for the medical profession, individually and collectively, to impress itself and its views on the members of the Medical Advisory Board of the Committee on Economic Security. Bear in mind that the physicians on this board were selected largely not as representatives of the medical profession but as physicians who have expressed in various ways definite points of view in relationship to the social changes that seem to be in progress.

PROGRESS IN THE STUDY OF EVOLUTION

In the Penrose Memorial Lecture before the American Philosophical Society, the Princeton biologist Edwin G. Conklin traces the progress of a generation in the study of evolution. A recapitulation of this instructive lecture¹ may be of interest. At the beginning of this century the study of evolution entered a new era. This study before had been based largely on observation and deduction. While the fact of evolution was accepted generally by scientists, the factors concerned were largely matters of personal opinion and speculation. As Conklin says, what seemed probable to one seemed very improbable to another. But in 1900 Mendel's principles of heredity were rediscovered and genetics, a new experimental science of heredity, was born. The actual laws of heredity begin at last to be established. In the following year De Vries published his great work on the mutation of the evening primrose, which was living evidence of evolution under experimental conditions. The mutation theory of evolution is now well established. Mutations are inherited and represent changes in the germ cells, while changes in developed organisms, fluctuations, are not inherited. Herein, Conklin points out, lies the chief distinction between the older and the newer views of evolution, which hold that the changes are wrought first in the germ cells. Almost at the same time as Mendel's principles of heredity and as the mutation theory were recognized came the discovery of the relation of the phenomena in question to the germ cells.

On the average the offspring inherits as many traits from one parent as from the other. Since it receives an equal number of chromosomes from each parent, there seemed good reason to conclude that the chromo-

somes carry the factors of inheritance. Now certain differences were found in the chromosomes of males and of females, the male lacking certain hereditary materials found in the female, on which sex depends. "Thus the initial cause of sex, which had been a subject of speculation for thousands of years, was found in a difference in certain chromosomes in the two sexes." The next step was the discovery that the parental chromosomes unite into synaptic pairs and that the subsequent separation in the reduction division exactly parallels the mendelian segregation of characters, thus explaining mendelian inheritance. In this establishment of the cytologic basis of inheritance, American investigators have taken a leading part.

Within the first five years of this century the mendelian law of heredity, the mutation theory of evolution, the failure of selection to build new species, and the chromosomal mechanisms of sex determination and inheritance were established. Today the problems of evolution center largely in the germ cells. "The germ cells are the only living bonds not only between generations but also between species, and contain the physical basis, not only of heredity but also of evolution." Remember that the older naturalists thought of evolution only as changes in mature organisms under environmental influences. Among the significant advances of the most recent study of evolution Conklin mentions especially analysis of the causes of mutations. These may be caused by changes in the numbers and association of whole chromosomes, changes in the composition of individual chromosomes, and changes in the ultimate inheritance units or genes themselves. Numerous examples are cited of new mutant species by changes in the whole chromosomes. Mutations caused by changes in the genes (which lie in the chromosomes) have been found in almost all animals and plants bred in large numbers under experimental conditions. The animal most used is the vinegar fly, "the most famous animal in the world" in the field of evolution or heredity. This fly can be bred easily, so that a new generation is obtained every twelve days; it has a large number of readily recognizable hereditary characters, and it has only four pairs of chromosomes, readily distinguishable. More than 500 mutations, affecting various parts, have been found in this fly during the past twenty-five years. By ingenious methods, particular mutant genes have been located in particular chromosomes and even in particular regions of these. The leader in this study has been Thomas Hunt Morgan, who received the 1933 Nobel prize in medicine in recognition of the fundamental importance of his work. The nature of the changes in the genes that result in mutations is not known. "The fact that it may affect one gene and not another similar one that is not more than one thousandth of a millimeter away would seem to indicate that it is not some general environmental influence." X-rays and radium may cause gene mutations. Heating the eggs sufficiently to kill most of

1. Conklin, E. G.: A Generation's Progress in the Study of Evolution, *Science* 80: 147 (Aug. 17) 1934.

them may result in survivors of new types. We are now at the very beginning of any understanding of the nature and full significance of gene activity in embryology and in evolution. Conklin points out that mutations generally are regressive and seem to lead nowhere. This weakness in the mutation theory is met by the possibility that natural selection eliminates useless mutations and slowly builds up "the marvelous combinations of useful adaptations that all organisms possess." Adaptations, says Conklin, are still the greatest problem of biology.

Is Darwin's principle of the elimination of the unfit and the survival of the fit the only explanation? Darwin relied on inheritance of the effects of use and disuse as an aid in natural selection, but the evidence of genetics shows conclusively that these effects are not inherited. Conklin follows Weismann in extending the principles of selection to many of the reactions of organisms, which are, he says, generally able to select between that which is satisfactory and that which is not. "No one can at present explain this property of life, but apparently it is a general characteristic of all living things." In other words, the selection is not exclusively by way of the environment, as the organism itself can select or reject. As Weismann said, the selection principle "does not create the primary variations but it does determine the paths of development which these follow." Thus we are brought face to face again with fundamental problems of life from a new angle.

THE PINEAL BODY

Of the organs reputed to have an internal secretion, the pineal body has thus far successfully eluded all efforts to determine its function. As patients with tumors of this organ have been found to exhibit changes characteristic of precocious puberty, a relationship of the pineal body to sexual physiology has been postulated. But the results of pinealectomy in the hands of different investigators have been conflicting and confusing. Uniform effects on the primary or secondary sexual apparatus in either male or female could not be elicited.

The discovery independently by Silberstein and Engel¹ in Vienna and by Saphir² in Chicago that the pineal body contains estrogenic substance adds to the problem of the physiologic rôle of this organ. Silberstein and Engel worked with the pineal bodies of steers and calves, Saphir with those from human beings; the presence of estrogenic substance could readily be demonstrated by the Allen-Doisy technic after implantation of small pieces of pineal tissue into castrated mice. The Vienna investigators found that the estrogenic substance could not be extracted by alcohol, ethyl ether and acetone. This is a curious observation in view of

the fact that the estrogenic fractions of the ovary, placenta, blood and urine are known to be soluble in varying degrees in these liquids. The estrus-inducing factor of the pineal body could, however, be taken up by dilute alkali but not by dilute acid, from powder remaining after acetone extraction.¹ A 640 mg. pineal body of a steer was found to contain at least 16 mouse units of estrogenic substance,¹ while Saphir² reported that the human organs, weighing on an average about 150 mg., contained at least 2 to 3 mouse units each. The Chicago investigator found estrogenic activity in the pineal bodies of both men and women and in that of a child (sex not stated). A gonad-stimulating effect of pineal tissue could not be detected by injection either into mice² or into rabbits,¹ nor did the intramuscular implantation of this material into mature female mice notably affect their sexual cycles.²

The significance of these results is obscure. It remains still to be determined whether or not the estrogenic factor of the pineal body exerts any important normal function in the physiology of the sexual organs, male or female. It must be remembered, for instance, that estrogenic substance may regularly be found in the male, yet no definite normal function has yet been attributed to this factor in this sex. The relationship of the pineal estrus-inducing substance to that found in other organs, tissues or body fluids is, of course, not yet known.

It is therefore too early to speculate as to the activity of the pineal body in the normal animal. The important investigations of Silberstein and Engel and of Saphir appear, however, to constitute a significant step in the eventual elucidation of the function of this organ.

Current Comment

THE VITAMIN C CONTENT OF HUMAN TISSUES

The recent isolation of vitamin C, its identification and its synthesis have opened a new field for the investigation of the physiologic rôle of this substance in the organism. Harris and his co-workers¹ in England determined by chemical methods its rate of excretion in the urine following oral ingestion. It was suggested that this method might serve as a means of determining latent scurvy in patients before detectable clinical signs appear. More recently Yavorsky, Almaden and King² in this country have assayed also by chemical means the vitamin C content of various human tissues obtained at necropsy. Material was obtained from sixty-seven individuals ranging in age from birth to 70 years. Thirty-one were less than 10 years old; of these the vitamin C content of the tissues was so low in four that latent scurvy was evident. In six of

the remaining thirty-six patients the tissues were so depleted in the vitamin that the concentrations of the latter reached the levels found in terminal human or guinea-pig scurvy. While Yavorsky and his co-workers do not report the clinical diagnoses in the various individuals studied, they state that there had been no specific consideration of scurvy in any instance. A number of the patients apparently had been on dietaries low in the antiscorbutic factor for some time preceding admission to the hospital. The concentration and distribution of vitamin C in the various organs was found to correspond more or less closely with those in the guinea-pig. However, a wide range of variation occurred among the different patients. The results of the Pittsburgh investigators further suggest that chemical examinations of body fluids for vitamin C might be of considerable clinical value.

Association News

MEETING OF MEDICAL ADVISORY BOARD OF COMMITTEE ON ECONOMIC SECURITY

The Medical Advisory Board, appointed by Secretary Perkins, chairman of President Roosevelt's Committee on Economic Security, to advise the committee's technical staff in its study of programs of public health, medical care and health insurance, met in Washington on November 14 and 15. The board met in executive session with all its members present as follows: Drs. Walter L. Biering of Iowa, Rexwald Brown of California, James Deacon Bruce of Michigan, George W. Crile of Ohio, Harvey Cushing of Connecticut, Robert B. Greenough of Massachusetts, J. Shelton Horsley of Virginia, James Alexander Miller of New York, Thomas Parran Jr. of New York, George M. Piersol of Pennsylvania and Stewart R. Roberts of Georgia. Other persons attending the meeting included Edgar Sydenstricker, in charge of the medical and health phases of the studies of the Committee on Economic Security, I. S. Falk of the technical staff, and by invitation Dr. R. G. Leland and A. M. Simons of the Bureau of Medical Economics of the American Medical Association.

Nathan Sinai, Michael M. Davis and W. Frank Walker also met with the board as consultant staff members associated with the dental, hospital and public health advisory committees which have also been appointed by Secretary Perkins and which are to meet in the immediate future. The meeting was opened by short addresses from Secretary Perkins and Edwin E. Witte, executive director of the Committee on Economic Security. Secretary Perkins and Mr. Witte requested the close cooperation and advice of the medical profession in developing the health aspects of the President's program for economic security. Owing to the fact that the Medical Advisory Board will make its recommendations to the Committee on Economic Security no public statement of its deliberations was given out, but we are informed by Mr. Witte that the technical staff of the committee presented to the board tentative proposals on the three subjects above mentioned in extending and improving public services, tax supported medical care for dependents and other population groups affected with certain diseases and health insurance against illness.

Health insurance was discussed from the point of view of considering the details of a plan suitable to the various needs of the American people and the interests of the medical professions in the event that legislation on this subject is proposed by the administration. The board requested an extension of time for this study. Arrangements were effected whereby Dr. Leland and Mr. Simons will participate in this study with the technical staff. It is anticipated that the board will meet again within the next six weeks or two months.

THE ATLANTIC CITY SESSION

Application for Space in the Scientific Exhibit

Application blanks are now available for space in the Scientific Exhibit at the Atlantic City session of the American Medical Association, June 10-14, 1935. The Committee on Scientific Exhibit requires that all applicants fill out the regular application form and requests that this be done as early as convenient.

Persons desiring application blanks should address a request to the Director, Scientific Exhibit, American Medical Association, 535 North Dearborn Street, Chicago.

MEDICAL BROADCASTS

Columbia Broadcasting System

The American Medical Association broadcasts on a western network of the Columbia Broadcasting System each Thursday afternoon on the Educational Forum from 4:30 to 4:45, central standard time. The next two broadcasts will be delivered by Dr. W. W. Bauer. The titles will be as follows:

November 29. Holiday; no broadcast.
December 6. Keep Fighting Diphtheria.
December 13. Shopping for Health.

National Broadcasting Company

The American Medical Association broadcasts under the title "Your Health" on a Blue network of the National Broadcasting Company each Tuesday afternoon from 4 to 4:15, central standard time. The next three broadcasts will be as follows:

November 27. Dollars and Disease, Morris Fishbein, M.D.
December 4. The Quick Lunch, W. W. Bauer, M.D.
December 11. Care of the Handicapped, Morris Fishbein, M.D.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARKANSAS

Personal.—Dr. Walter C. Overstreet, Jonesboro, has resigned as health officer for Craighead County.—Dr. Sherod A. Drennen was elected acting mayor of Stuttgart, October 3.

Society News.—Dr. Arthur B. Chase, Oklahoma City, among others, addressed the Tenth Councilor District Medical Society at Fort Smith, September 18, on "Pain in Heart Disease."—At a meeting of the Mississippi County Medical Society in Blytheville, October 2, Drs. Robert G. Henderson and John P. Henry, Memphis, Tenn., discussed skin diseases and allergy, respectively.—The Pope County Medical Society was addressed at Russellville, October 11, by Drs. John M. Smith on "Gallbladder Disease and Associated Pathology" and Robert H. Hood, "Dietetic Treatment of Gallbladder Disease."—Speakers before the Fifth Councilor District Medical Society at Camden, October 11, were Drs. Hugh L. Moore and George L. Carlisle, Dallas, Texas, and James A. Warner, St. Louis.—At a meeting of the Pulaski County Medical Society in Little Rock, October 1, Drs. John L. Kantor, New York, and Paul B. Magnuson, Chicago, discussed "Functional Disturbances of the Gastro-Intestinal Tract" and "Diagnosis of the Causes of Low Back Pain," respectively. Dr. Andrew C. Ivy, Chicago, addressed the society, October 6, on "Etiology and Therapeutic Rationale of Peptic Ulcer."

CALIFORNIA

Dr. Ashley Named Health Officer.—Dr. Nilton N. Ashley has been appointed health officer of Oakland, succeeding Dr. Arthur Hieronymus, who has held the position since 1931. Dr. Ashley is 44 years of age and a graduate of the University of Louisville School of Medicine.

Medical Board Re-elected.—At a meeting of the state board of medical examiners in Sacramento in October, the following physicians were re-elected: William R. Molony, Los Angeles, president; Clark L. Abbott, Oakland, vice president, and Charles B. Pinkham, San Francisco, secretary-treasurer.

University News.—Dr. Robert F. Loeb, associate professor of medicine, Columbia University College of Physicians and Surgeons, New York, conducted a clinic on diabetic acidosis before the faculty and students of the University of California Medical School, October 13. Dr. Frank B. Young, Long Beach, addressed the faculty and students, October 10, on "The Antiquity of Diseases."

County Society Library Opened.—The formal opening of the library of the Los Angeles County Medical Association took place, November 27, in the auditorium of the association building. Dr. George Dock, president, made the presentation of the Barlow Medical Library on behalf of the medical library association, and Dr. Philip H. Stephens, president of the county society, the speech of acceptance. Dr. Herbert M. Evans, professor of anatomy and Herzstein professor of biology, University of California Medical School, gave an address, and greetings were offered by Miss Louise Ophuels, vice president of the library association.

DISTRICT OF COLUMBIA

Dr. Fowler Retires as Health Officer.—The retirement of Dr. William C. Fowler, health officer of the District since 1918, will be effective November 24, when he will reach the statutory retirement age of 70. Dr. Fowler graduated from Georgetown University School of Medicine in 1888, and became associated with the health department in 1894 as sanitary officer. From 1906 to 1907 he served as chief medical inspector in charge of the contagious disease service and in 1917 was made assistant health officer. The following year he was appointed health officer. No successor to Dr. Fowler has been announced, but newspapers reported that a reorganization of the department is being contemplated and until this takes place Dr. Edward J. Schwartz will be acting health officer. The committee to study the reorganization will be composed of representatives of the District medical society, the U. S. Public Health Service, and the hospitals of Georgetown and George Washington universities.

FLORIDA

Health at Miami.—Telegraphic reports to the U. S. Department of Commerce from eighty-six cities with a total population of 37 million, for the week ended November 10, indicate that the highest mortality rate (20.3) appears for Miami, and the rate for the group of cities as a whole, 11.1. The mortality rate for Miami for the corresponding period last year was 4.7, and for the group of cities, 10.4. The annual rate for the forty-five weeks of 1934 was 11.3 as against a rate of 10.8 for the corresponding period of the previous year. Caution should be used in the interpretation of these weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits or that they have a large Negro population may tend to increase the death rate.

ILLINOIS

Dental Survey.—The state department of health and the Illinois State Dental Society are cooperating in a fall and winter dental health survey of school children. Diet and periodic dental inspections with the aim of preventing tooth decay will be emphasized. In the educational program to coincide with the survey, prenatal care, especially from the standpoint of the diet of prospective mothers, and the diet of children will be particularly stressed in connection with efforts to prevent dental decay. The periodic inspection of teeth and the prompt correction of caries were also emphasized.

Society News.—At a meeting of the Iowa and Illinois Central District Medical Association in Moline, October 31, Dr. Foster Kennedy, New York, discussed "The Interdependence of Neurology, Psychiatry and General Medicine," and Dr. Grandison D. Royston, St. Louis, "The Care of Obstetrical Damage to the Cervix and Pelvic Supports."—Speakers before the Peoria City Medical Society, November 6, were Drs. Clarence Baxter Brown on "Ectopic Pregnancy"; Emil Z. Levitin, "Schizophrenia"; William A. Hinckle, "Anatomical Causes of Proctologic Pathology," and Harry A. Durkin, "Prognostic Consideration of Heart Diseases."

Chicago

American Medical Association Night.—The Chicago Medical Society designated its meeting, November 21, "American Medical Association Night." Speakers were Drs. Walter L. Bierring, Des Moines, Iowa, President of the Association, on "Plans for Economic Security"; William C. Woodward, director, Bureau of Legal Medicine and Legislation, "The Health Insurance Program," and Edward H. Cary, Dallas,

Texas, past president, "Some Suggestions Toward Medical Cooperation." A dinner in honor of the guest speakers preceded the meeting. Other officials of the Association were on the reception committee.

Society News.—The Hebrew University Society was recently organized with Dr. Maurice Lewison as president. The purpose of the society is to support the Hebrew University in Palestine, particularly the university hospital and medical center, which is being built on Mount Scopus. Other officers are Drs. Alfred A. Strauss, vice president; Mayer H. Lebensohn, treasurer, and Charles Newberger, secretary. The society is affiliated with the American Jewish Physicians Committee of New York, of which Dr. Nathan O. Ratnoff is president and Dr. Emanuel Libman is chairman of the executive committee. —Dr. Joseph L. Miller will deliver the presidential address at the nineteenth annual meeting of the Institute of Medicine of Chicago, December 4; his subject will be "The Influence of Claude Bernard's Experimental Methods on Medicine."

KANSAS

Birth Registration Campaign.—The Kansas State Board of Health, the federal bureau of the census and the state emergency relief committee are sponsoring a campaign to insure correctness of records and to emphasize legal, social and economic importance of birth registration. Cards will be mailed to every family in Kansas, enclosing birth information, with a request that it be completed for return to the vital statistics department of the state board of health. It is believed that this plan will strengthen the registration of the past year.

Society News.—Dr. Walter L. Bierring, Des Moines, Iowa, President, American Medical Association, will address the Shawnee County Medical Society, December 3.—Dr. Wilfred Cox, Wichita, read a paper on "Dermoid Cysts of the Ovary" before the Sedgwick County Medical Society, October 16.—At a joint meeting of the Clay and Washington county medical societies in Clay Center, October 10, Dr. Edward H. Skinner, Kansas City, Mo., discussed "Preventable and Curable Conditions in the Field of Malignancy."—Dr. Thomas J. Sims Jr., Kansas City, addressed the Wyandotte County Medical Society, November 20, on "Obstetrical Anesthesia and Analgesia." Speakers before the society, October 16, were Drs. Harry R. Wahl and Russell W. Kerr, Kansas City; their subjects were "Primary Carcinoma of Lungs with Marked Mediastinal and Cardiac Extension" and "Extensive Diffuse Carcinoma of the Stomach with Widespread Visceral Metastases." G. Farrell Webb, D.D.S., discussed "Dental Infection as Related to Medicine."

KENTUCKY

State Medical Election.—Dr. Joshua B. Lukins, Louisville, was chosen president-elect of the Kentucky State Medical Association at the annual meeting in Harlan in October, and Dr. Carl C. Howard, Glasgow, was installed as president. Vice presidents elected were Drs. Benjamin F. Robinson, Lexington; Robert L. Collins, Hazard, and Reason T. Layman, Elizabethtown. The next meeting will be held in Louisville.

Society News.—Dr. James W. Bruce addressed the Jefferson County Medical Society, Louisville, November 5, on "Cutaneous Burns." Dr. John J. Moren will speak, November 19, on "Relation of Trauma to Diseases of the Nervous System."—Dr. Adolph O. Pfingst addressed the Louisville Medico-Chirurgical Society, November 9, on "Internal Carotid Cavernous Sinus Aneurysm in Infancy."—Dr. George A. Hendon was the speaker before the Louisville Surgical Society, November 22, on "Mechanical Drainage."—Dr. J. Oliver Knight addressed the Louisville Urological Society, November 27, on "Benign Hypertrophy of the Prostate."—Dr. Milton Smith Lewis, Nashville, Tenn., addressed the Third District Medical Society at Bowling Green, October 17, on treatment of eclampsia.

MASSACHUSETTS

The Dunham Lectures at Harvard.—Dr. Ulrich Friedemann, formerly professor of internal medicine at the University of Berlin and director of the division of infectious diseases at the Virchow Krankenhaus, will deliver three lectures at Harvard Medical School under the Edward K. Dunham Lectureship for the Promotion of the Medical Sciences, December 4, 6 and 11. The first two lectures will be on "Distribution of Dyes, Drugs and Toxins in the Animal Body," and the third on "The Pathogenesis of Diphtheria."

Personal.—Dr. Clifford D. Moore has been named chief executive officer of the Boston Psychopathic Hospital, succeeding the late Dr. Samuel S. Cottrell.—Dr. Lawrence J.

Henderson, professor of biological chemistry, Harvard University Medical School, was awarded the honorary degree of doctor of science by the University of Cambridge, England, October 22.—Dr. C. Macfie Campbell, professor of psychiatry, Harvard University Medical School, Boston, has recently been elected president of the Massachusetts Psychiatric Society; Dr. Charles E. Thompson, Gardner, vice president, and Dr. Oscar J. Raeder, Boston, secretary.—Dr. Walter B. Cannon, George Higginson professor of physiology at Harvard Medical School, has been granted leave of absence from March 15 to Sept. 1, 1935.

MISSISSIPPI

Personal.—Dr. Romeo R. Halfacre, assistant superintendent of the state asylum, Jackson, was recently appointed superintendent of the Ellisville State School by the state board of administration, succeeding Dr. Hugh L. McKinnon, Hattiesburg.—Dr. James T. Googe, Lexington, has been appointed health officer of Copiah County, succeeding Dr. William L. Little, Wesson, who has been conducting the unit on a part time basis. With Dr. Googe's appointment, the unit has been restored to a full time basis.—Dr. James V. May, Port Gibson, has retired from active practice on account of illness. He served as president of the Claiborne County Medical Society for several years.

Graduate Course in Obstetrics.—Clinics and lectures on antepartum and postpartum care will be available for group or individual consultation, beginning January 1, through the state committee on graduate medical education, under the direction of Dr. Maxwell E. Lapham, Philadelphia. The state medical association made the course possible at its meeting in Natchez last May when it appropriated \$1,500 and requested the Commonwealth Fund to cooperate financially with the association, the Tulane University of Louisiana School of Medicine and the state board of health. Classes of physicians will be organized in convenient centers to meet for two hours one day a week for eight or ten consecutive weeks. The first centers proposed are Natchez, Centreville, McComb, Columbia and Silver Creek.

NEW HAMPSHIRE

Health Insurance Opposed.—The Merrimack County Medical Society at a meeting in Concord, October 31, recorded its opposition to the adoption of a health insurance plan by the state or national government.

Dr. Bielschowsky Joins Dartmouth.—Dr. Alfred A. Bielschowsky, until recently professor of ophthalmology at the University of Breslau, Germany, has joined the department of research in physiologic optics at Dartmouth Medical School, Hanover, for six months of special work. Dr. Bielschowsky had been associated with the University of Breslau since 1923 and before that had been a member of the faculties of the universities of Marburg and Leipzig.

NEW JERSEY

Personal.—Dr. Martin H. Collier, Camden, was elected president of the eastern section of the American Sanatorium Association at its annual meeting at White Haven, Pa., October 7-8.—Dr. William C. Raughley, Berlin, was honored by the Camden County Medical Society at a meeting in Camden, October 2, in recognition of his fifty years of medical practice. He received a certificate of honor.

Theobald Smith Receives Another Award.—The New Jersey Health and Sanitary Association at its annual dinner, November 16, presented its annual award for meritorious service to Dr. Theobald Smith, director emeritus of the Department of Plant and Animal Pathology, Rockefeller Institute for Medical Research, Princeton. Dr. Smith could not attend the dinner because of illness, and the award, a bronze plaque, was accepted for him by Dr. Carl TenBroeck, present director of the Princeton branch. Mr. James E. Brooks, Newark, made the presentation, reviewing Dr. Smith's career as physician, teacher, student and scientist.

Meeting of Physicians and Pharmacists.—The Bergen County Medical Society met jointly with the Bergen County Pharmaceutical Association in Hackensack, November 13, with the following program: Charles W. Ballard, Ph.D., professor of materia medica, Columbia University College of Pharmacy, New York, "The Physician, the Patient and the Pharmacist"; Dr. Walter S. McClellan, medical director, Saratoga Springs Commission, New York, "Hydrotherapy and Indications for the Use of Natural Carbonated Mineral Waters"; Adolph F. MacQuier, Pharm.M., professor of pharmacy, Rutgers University, "Relationship of the Drug Store to the Physician";

Robert P. Fisehelis, Ph.M., Trenton, president of the American Pharmaceutical Association, "Problems Requiring Cooperation of the Allied Medical Professions."

NEW YORK

Diphtheria Campaign.—The departments of health and education of the city of Albany and the Medical Society of the County of Albany are cooperating in a campaign for the inoculation of children against diphtheria. Cooperating physicians have agreed to perform the inoculations for a nominal fee during the campaign, the city to pay for those unable to pay for themselves. The health department has agreed not to administer the treatment until January 1, and both city departments have agreed not to conduct diphtheria clinics in public or parochial schools during the present school year.

Graduate Lectures in Rochester.—The following series of lectures was presented under the auspices of the Medical Society of the State of New York before the Medical Society of the County of Monroe in Rochester, October 22-26:

- Dr. Arthur C. DeGraff, New York, Normal Functions of Small Blood Vessels and Alterations Produced by Disease.
- Dr. William Goldring, New York, Kidney Function as Affected by Disturbance of Circulation in the Kidney Itself.
- Dr. De Graff, Cardiac Function as Affected by Disturbance of Circulation in the Heart Itself.
- Dr. Norman Jolliffe, New York, Liver Function as Affected by Disturbance of Circulation in the Liver Itself.
- Dr. Clarence de la Chapelle, New York, A Consideration of the Extremities as Affected by Disturbance of Peripheral Circulation.

New York City

Tree Memorial to Madame Curie.—The sixty-seventh birthday of the late Madame Marie Curie, November 7, was observed by the planting of a tree in City Hall Park, with ceremonies in which Mayor La Guardia and Park Commissioner Robert Moses participated. Various French and Polish societies and the consul generals of France and Poland also took part.

Endowment for Long Island College.—The late Mr. Frank L. Babbott, who died in Brooklyn in December 1933, bequeathed a fund of approximately \$1,500,000 to the Long Island College of Medicine, Brooklyn, as a special endowment fund, the income from which is to be applied to the furtherance of medical education and research. Mr. Babbott's son, Dr. Frank L. Babbott Jr., is president of the college.

Hospitals' Work Increases.—The United Hospital Fund has published the results of a study of hospital service during the period from 1927 to 1933 showing a heavy increase in the hospital population. The total number of beds increased from 33,535 in 1927 to 41,064 in 1933 and the annual number of patients increased from 549,824 in 1927 to 673,767 in 1933. The largest increase was found in visits to outpatient departments, from 4,183,933 in 1927 to 6,843,025 in 1933. Shifting of patients from voluntary to municipal hospitals was shown by a change in the percentages cared for by the two groups: 65 per cent of the patients were cared for in voluntary hospitals in 1933 as compared with 72.2 per cent in 1927. Another study showing the operating expenses of twenty-seven general hospitals of the fund disclosed that expenditures in the inpatient departments in 1928 were \$13,916,538, toward which earnings from patients provided 74.2 per cent; in 1933 the expenses amounted to \$12,493,568, with earnings of 61.8 per cent. In 1928, earnings from outpatient departments paid 61.9 per cent of the operating expenses and in 1933 only 54.9 per cent.

Examination for Psychiatrist to Board of Education.—The board of examiners of the New York City Board of Education announces an examination for license as psychiatrist open to men and women applicants for service in the bureau of child guidance. November 30 is the final date for the receipt of applications, which may be obtained at the offices of the board or which will be sent on receipt of a request accompanied by a large stamped, self-addressed envelop. Graduates from recognized medical schools with three years' experience in the practice of psychiatry are eligible; one year must have been spent in institutions for mental disease and two in an organization or clinic for study and treatment of personality and behavior disorders of children. The present age limits for this examination are 35 to 45 years, but the board of education has been asked to lower the limit to 30 years and therefore tentative applications will be received from persons under 35 and over 30. The examination will be in five parts. The first is a thesis of from 7,500 to 10,000 words on the functions and duties of a psychiatrist in maintaining the effective service of a child guidance bureau in a large city school system. Part II is an evaluation of experience, record and personal research studies. Parts III, IV and V will be given only in

New York City subject to the call of the examiners; they include submission of case records, an interview test and a medical examination. The salary will be from \$6,000 to \$7,000 a year. For information address the Board of Examiners, 500 Park Avenue, New York.

NORTH DAKOTA

Personal.—Dr. and Mrs. Jess H. Moeller, Maddock, were honored recently when 200 friends gathered at their home to observe the twenty-fifth anniversary of their residence in the city; Dr. Moeller was presented with a purse of silver.

Society News.—Dr. Howard K. Gray, Rochester, Minn., addressed the Devils Lake Medical Society in October on "Surgery of the Biliary Tract."—Dr. Rosslyn B. Mitchell, Winnipeg, Manit., addressed the Grand Forks Medical Society, recently, on toxemia in pregnancy.—The North Dakota Anti-Tuberculosis Association celebrated the twenty-fifth anniversary of its founding, October 22.

OHIO

Society News.—Dr. Frank H. Lahey, Boston, addressed the Mahoning County Medical Society, Youngstown, November 20, on "Cancer of the Rectum and Colon."—Speakers at a meeting of the Adams County Medical Society, Manchester, October 17, were Drs. Frederick C. Leeds, Winchester, on "Puerperal Infection"; Wells Teachnor, Columbus, "Cancer of the Rectum and Colon," and Andrew R. Carrigan, Manchester, "Acute Poliomyelitis."—Dr. Hugh Wellmeier addressed the Miami County Medical Society, Piqua, October 12, on "Congenital Syphilitic Conditions in Children."—Dr. Walter G. Stern, Cleveland, lectured on treatment of fractures at a meeting of the Columbiana County Medical Society, Lisbon, October 16.—Dr. Isidor S. Ravdin, Philadelphia, addressed the Stark County Medical Society, Canton, October 9, on acute appendicitis.—Drs. George C. Malley, Parkersburg, W. Va., and Martha Margaret O'Neal, Zanesville, addressed the Muskingum County Academy of Medicine, Zanesville, October 2, on "Intracranial Hemorrhage of the New-Born" and "Pyloric Stenosis in the New-Born," respectively.—Dr. Frederick C. Herrick, Cleveland, addressed the Summit County Medical Society, Akron, November 6, on "Purulent Appendicitis with Rupture of the Appendix."—Dr. Virgil S. Counsellor, Rochester, Minn., addressed the Montgomery County Medical Society, Dayton, on "Conservatism in Gynecology," October 19, and Dr. Sumner L. S. Koch, Chicago, November 2, on "Acute Infections of the Hand."—Dr. John Alexander, Ann Arbor, Mich., addressed the Cleveland Academy of Medicine, November 16, on "The Present Status of Chest Surgery."

PENNSYLVANIA

Society News.—The Fayette County Medical Society held its fall clinic November 8, with Drs. Evan W. Meredith, Howard G. Schleiter and John F. McCullough, all of Pittsburgh, conducting surgical, medical and roentgenologic clinics, respectively.—Dr. James A. Cahill Jr., Washington, D. C., addressed the Lackawanna County Medical Society, November 6, on surgical consideration of acute conditions in the abdomen.—Dr. Philip F. Williams, Philadelphia, addressed the Cambria County Medical Society, Johnstown, November 8, on "The Toxemias of Pregnancy."—Dr. Frank H. Lahey, Boston, addressed the Delaware County Medical Society, Chester, November 5, on "Hyperthyroidism and Its Complications with Other Diseases."

Philadelphia

Public Health Night.—The Philadelphia County Medical Society held a "Public Health Night," November 14, with the following speakers: Dr. Henry F. Smyth, assistant professor of industrial hygiene, University of Pennsylvania, "Studies of Philadelphia Air Conditions"; David H. Wenrich of the zoological laboratory, University of Pennsylvania, "Amebiasis and the Carrier," and Franz C. Schnelkes, New York, "Chlorine and the Prevention of Disease."

Wards Named for Hospital Staff Members.—The medical board of the Philadelphia General Hospital announces that several wards will be named for distinguished physicians who have been members of the hospital staff, with dedicatory ceremonies December 4 in the auditorium of the hospital. One building will be named the Sir William Osler Building and the wards will be dedicated to the memory of the following physicians: Drs. Frederick P. Henry, Benjamin Rush, William W. Gerhard, David Hayes Agnew, Horatio C. Wood, C. Lincoln Furbush, Charles K. Mills and J. Chalmers DaCosta.

SOUTH CAROLINA

Malaria Has Increased.—The state department of health recently reported that 800 more cases of malaria had occurred in the state up to the end of September than occurred in the corresponding period of last year. The increase has been noticed especially since July; more than 300 cases per month have been reported. Malaria control work is proceeding slowly because of lack of funds, according to the state health officer, Dr. James A. Hayne, Columbia.

Society News.—Speakers at a meeting of the Tri-County Medical Association (Orangeburg, Bamberg and Calhoun Counties) in Elloree, September 20, were Drs. Samuel E. Harmon, president-elect of the South Carolina Medical Association, on "Modern Economic Problems of the Physician"; Orlando B. Mayer, "Influenza and Pneumonia with Special Reference to Treatment and Use of Oxygen"; George H. Bunch, "Suppurative Pericarditis"; James Richard Allison, "Cancer Information and Propaganda"; Thomas A. Pitts, "Radiation"; William R. Barron, "Prostatic Obstruction." All the speakers are from Columbia.

VIRGINIA

Personal.—Dr. Ernest L. Stebbins has resigned as health officer of Henrico County to join the staff of the New York State Department of Health, Albany.—Dr. William R. Bond, professor of physiology, Medical College of Virginia, Richmond, has been granted a leave of absence for the remainder of the academic year.

Officers of Special Societies.—Several societies that met in conjunction with the Medical Society of Virginia in Alexandria early in October elected officers as follows: Dr. Robert V. Funsten, University, was chosen president and Dr. Bernard H. Kyle, Lynchburg, secretary of the Virginia Orthopedic Association; Drs. William P. McDowell, Norfolk, and W. Ambrose McGee, Richmond, president and secretary, respectively, of the Virginia Pediatric Society; Drs. John H. Neff, University, and Linwood D. Keyser, Roanoke, president and secretary, respectively, of the Virginia Urologic Society.

WISCONSIN

University News.—The regents of the University of Wisconsin, Madison, have appointed a committee to work out plans for using a \$450,000 bequest left to the university by Miss Jennie Bowman earlier in this year for the establishment of a cancer institute. Members of the committee are Glenn Frank, LL.D., president of the university; Dr. Charles R. Bardeen, dean of the medical school, and Edwin B. Fred, Ph.D., dean of the graduate school.

Society News.—Drs. Albert C. Broders, Rochester, Minn., and William D. Stovall, Madison, addressed the Winnebago County Medical Society, Oshkosh, October 30, on "Grading of Cancer in Its Relationship to Prognosis and Treatment" and "The State Program for the Control of Cancer," respectively.—Dr. James C. Sargent, Milwaukee, addressed the Dane County Medical Society, Madison, October 9, on "Urinary Tract Stones."—Drs. Eugene S. Knox, Green Bay, and Herman A. Heise, Milwaukee, addressed the Racine County Medical Society, Racine, October 18, on "Gas Gangrene" and "Detention of Alcohol in Body Fluids (Quantitatively) and the Factor of Alcohol in Automobile Accidents," respectively.

GENERAL

Society News.—Dr. Fred M. Hodges, Richmond, Va., was chosen president of the American Roentgen Ray Society at its annual meeting in Pittsburgh, September 25-28, and Dr. George W. Grier, Pittsburgh, was installed as president. Vice presidents elected are Drs. Lyell C. Kinney, San Diego, Calif., and John Sproull, Haverhill, Mass., and the secretary is Dr. Eugene P. Pendergrass, Philadelphia. The next meeting will be held in Atlantic City in September 1935.—Dr. David Riesman, Philadelphia, was named president-elect of the International Postgraduate Medical Assembly of North America at its annual meeting in Philadelphia, November 5-9.—Dr. Thomas J. Collier, Atlanta, Ga., was elected president of the Associated Anesthetists of the United States and Canada at its meeting in Boston, October 18, and Dr. F. Hoeffler McMechan, Rocky River, Ohio, was reelected secretary. The next annual session will be held at Atlantic City, June 10-14.

Registry of Brain Tumors at Yale.—A series of about 2,000 tumors of the central nervous system collected by Dr. Harvey Cushing, now Sterling professor of neurology at Yale University School of Medicine, New Haven, during his service at Johns Hopkins in Baltimore and the Peter Bent Brigham Hospital, Boston, has been installed at Yale. It is

intended that these elaborately catalogued specimens be made useful as far as possible to those interested and it is hoped that the collection will be increased. It is thought that it will be of use to those who encounter rare tumors that they wish to have identified if possible and concerning which they may desire information, particularly on the basis of type prognosis. Any one who may wish to send specimens for diagnosis or may seek information of other sorts is welcome to do so, an announcement states. The following physicians have consented to act as an advisory board:

Dr. Percival Bailey, professor of surgery and neurology, University of Chicago.

Dr. Francis C. Grant, assistant professor of neurological surgery, University of Pennsylvania School of Medicine, Philadelphia.

Dr. Samuel C. Harvey, professor of surgery, Yale University School of Medicine, New Haven.

Dr. George J. Heuer, professor of surgery, Cornell University Medical College, New York.

Dr. Wilder G. Penfield, professor of neurology and neurological surgery, McGill University Faculty of Medicine, Montreal.

Dr. Ernest Sachs, professor of clinical neurological surgery, Washington University School of Medicine, St. Louis.

Dr. William P. Van Wagenen, associate professor of neurological surgery, University of Rochester School of Medicine and Dentistry, Rochester, N. Y.

Dr. Simeon B. Wolfbach, Shattuck professor of pathological anatomy, Harvard University Medical School, Boston.

Dr. Louise C. Eisenhardt is curator of the collection.

Changes in Status of Licensure.—The State Board of Medical Examiners of Alabama announces the following action:

Julius G. Henry, Akron, license reinstated, August 21.

At a meeting of the Georgia State Board of Medical Examiners, October 11, the licenses of the following to practice medicine were revoked for violations of the Harrison Narcotic Act:

Dr. Alva H. Weathers, Atlanta.

Dr. William R. Thomas, St. Mary's.

Dr. Loring B. Palmer, Atlanta.

Dr. Luis Balmori, McAdenville, N. C.

At a recent meeting of the Kansas State Board of Registration and Examination, the following action was taken:

Dr. Matthew L. Miller, Coffeyville, license revoked because of conviction on felony charge.

Dr. Christopher C. Kesner, LeRoy, license restored.

The State Board of Health of Missouri recently reported the following action:

Dr. Dawsey Ryan, Bernie, placed on probation for one year, October 26, for excessive use of alcohol.

The Board of Registration in Medicine of Massachusetts reports the following actions:

Dr. Harold Van Gaasbeek, Chicopee Falls, license revoked, July 12, because of his conviction in court as an accessory before and after the fact in an abortion.

Dr. Everett D. Hooper, Boston, license restored, August 30.

The Illinois State Department of Registration and Education reports the following action:

Dr. Gilbert H. Wynekoop, Chicago, license revoked, October 15, because he was adjudged insane.

Dr. Alice Lindsay Wynekoop, Chicago, license suspended, October 15, pending the ultimate disposition of the appeal from the order of conviction in the criminal court of Cook County, the suspension to become a revocation in the event that the order of conviction is affirmed. Dr. Wynekoop was sentenced to prison following her conviction of murder.

Dr. John A. Newhouse, Caledon East, Ont., license revoked, October 11, for narcotic violation.

Dr. Archibald L. Calvin, Chicago, license revoked, October 11, following his conviction of manslaughter.

The Indiana State Board of Medical Registration and Examination reports the following action taken in October:

Dr. William Hamlin Curtiss, San Diego, Calif., license revoked for violation of the Harrison Narcotic Act.

Dr. Ralph K. Brown, New Albany, license revoked for violation of the Harrison Narcotic Act. Dr. Brown was recently sentenced to Fort Leavenworth.

The Texas State Board of Medical Examiners has reported the following revocations of licenses during the past year:

Richard L. Smith, Waco; Gustav R. Gerson, League City; John C. Hudson, Cedar Hill, and James L. Rountree, Argo, for narcotic addiction.

W. D. Yearly, Dallas, for violation of five year suspension of license.

Edgar M. Hughes, Truscott, because of commitment to a hospital for mental disease.

The New Jersey Board of Medical Examiners, at a meeting September 19, took the following action:

Dr. Charles F. Baxter, Paterson, license revoked for conviction of a crime involving moral turpitude; namely, obtaining money under false pretenses.

Annual Report of Red Cross.—Physical handicaps and health defects affecting 240,000 children were treated and corrected through the activities of the American Red Cross in 1933, according to the annual report, issued October 27. The report shows that 770 public health nurses made more than a

million nursing visits to 154,000 patients, nearly 20 per cent of whom were maternity cases. Several hundred more nurses were engaged in teaching home hygiene and care of the sick to 62,000 students during the year. The nursing service furnished nurses for epidemics of typhoid and malaria and in several disasters, notably the Los Angeles floods and the Texas hurricane. The food and nutrition service reached more than 7,000 students during the year, families affected by unemployment being especially aided through instruction in food selection. Two special funds were administered, one of \$25,000 given by Will Rogers for public health work and one of \$15,000 given by Scottish Rite Masons for giving employment to "white collar" workers.

CANADA

Hospital News.—Hospitals and clinics in greater Winnipeg have recently agreed that no patient will be admitted to their outpatient departments for consultation or treatment except on the production of a letter from a private practitioner.—Dr. Ernest C. Menzies, Montreal, has been appointed superintendent of the provincial hospital at Fairville, New Brunswick, succeeding Dr. James V. Anglin, retired.

Personal.—Dr. Murray Maclaren, St. John, N. B., entertained the St. John Medical Society at a dinner at the Riverside Country Club, August 18, in celebration of the fiftieth anniversary of his graduation from the University of Edinburgh Faculty of Medicine. The society presented a silver tray to Dr. Maclaren.—Dr. Reginald O. Davison, director of the division of communicable diseases in the Saskatchewan Department of Health since 1922, has been appointed deputy minister of health for the province.

Society News.—Dr. Lorimer J. Austin, professor of surgery, Queens University Faculty of Medicine, Kingston, Ont., addressed the St. John Medical Society, September 14, on carcinoma of the colon.—Dr. George W. Rogers, Dauphin, was elected president of the Manitoba Medical Association at the annual meeting at Winnipeg in September. A feature of the meeting was a symposium on "Upper Right Abdominal Pain," presented by Drs. Donald C. Balfour and Byrl R. Kirklin, Rochester, Minn.; Charles H. Hunter and Brandur J. Brandon, Winnipeg, and Lewis J. Carter, Brandon. Dr. Louis B. Wilson, Rochester, Minn., made an address at a dinner sponsored by the Medical Alumni Association on "Present-Day Defects in Medical Education."—Dr. Hugh H. Christie, Esterhazy, was elected president of the Saskatchewan Medical Association at the recent annual meeting; Dr. George H. Lee, Shaunavon, honorary president.

Government Services

Surgeon General Cruises with Fleet

Rear Admiral Perceval S. Rossiter, surgeon general of the U. S. Navy, sailed from Norfolk on the U. S. S. *Langley*, October 12, to join the fleet at Guantanamo Bay, Cuba. According to the *Military Surgeon*, this is the first time a surgeon general of the navy has made an extended cruise with the fleet and observed medical department activities afloat at close range. Surgeon General Rossiter's trip included a cruise on the flagship of Admiral Joseph M. Reeves during exercises in West Indian waters and the Caribbean. He transferred to the hospital ship, the U. S. S. *Relief*, in the Canal Zone, on which he completed the voyage to the West Coast. He will inspect all naval medical departments on the West Coast before he returns to Washington, D. C., about the first of the year.

Selling Fraudulent "Warm Springs" Crystals

W. C. Dunham, Macon, Ga., has been sentenced to a year in the penitentiary and two of his associates are awaiting trial on a charge of conspiring to violate the Federal Food and Drugs Act by advertising and selling "Warm Springs Crystal Compound" as coming from Warm Springs, Ga. The company and its so-called crystals, which were found to be Glauber's salt, were disavowed in the beginning by the Warm Springs Foundation as having no connection with the springs except that the office was set up in the town. When the "crystals" began to appear in interstate commerce, members of the company were indicted by a grand jury. It was reported that the salt was bought at 2 cents a pound and sold for \$1.

LONDON

(From Our Regular Correspondent)

Oct. 27, 1934.

Examination of the Eyes of Air Pilots

The air ministry has issued revised regulations for medical examination of fitness for flying. Those for eye examination are of interest. The standard of visual acuity, without correcting glasses, is 6/6 distant vision in each eye. But the eye specialist may at his discretion recommend acceptance when the acuity is 6/9 (for short service commissions 6/12) provided it is correctable to 6/6 in each eye. For private flying and for navigators a certain allowance is made and correcting glasses are allowed to be worn, provided a degree of acuity can be attained, with or without glasses, equal to at least 80 per cent of the normal visual acuity for each eye taken separately, or 90 per cent for one eye and 70 per cent for the other. No candidate, generally speaking, will be passed who shows a manifest hypermetropia of 2 diopters or over. The reason for this is that the continued effort to focus on the retina is apt to induce a tonic action of the ciliary muscle and also of the internal recti. This tonic action produces errors of judgment of distance in flying. In addition, under the effects of high altitude loss of accommodation is liable to occur, so that a pilot cannot see his instruments and will be liable to make a bad landing.

Great importance is attached to muscle balance and visual judgment, as these play a greater part in accurate flying than visual acuity. It has been proved that lack of true ocular muscle balance is the most common cause of error in judgment in landing. Exophoric pilots tend to flatten out their aircraft too early, because they judge the ground to be nearer than it is, while esophoric pilots tend to fly into the ground. In addition to these there are "bad landers" from defective neuromuscular coordination. A test for muscular balance favored by the British air ministry is the Bishop-Harman adjustable diaphragm, which enables the field of vision of one eye to be separated entirely or partially from that of the other. The capacity to maintain an even ocular muscle balance (and therefore binocular vision) under increasing difficulty produced by progressively diminishing the overlap of the visual fields is thus tested. Both eyes must have good visual fields as tested by hand movements. Color vision must be normal, as in landing at night colored lights are used as signals.

Crossing Places for Pedestrians

The latest measure for the prevention of road accidents—the provision of marked crossing places for pedestrians—has been described in a previous letter. New regulations have been issued concerning them. There is no compulsion of the pedestrian to cross at the indicated places, but pedestrians who remain on a crossing longer than is necessary will be liable to a fine of \$10. The general effect of the new regulations is that at crossings where the traffic is controlled by police or automatic signals the pedestrian has the absolute right of way only when the traffic has been stopped by the policeman's hand or the signal light. At crossings not so controlled he has the right of way at all times and the traffic must give way to him. But he must go straight across and so hinder the traffic as little as possible. Vehicles must not stand on a crossing. The driver of every vehicle approaching a crossing must, unless he can see that there is no pedestrian thereon, proceed at such a speed that he can stop if necessary before reaching the crossing. Every pedestrian on the crossing shall have precedence of him. The Pedestrian's Association is not satisfied on one point. The

minister of transport has not implemented his undertaking that a driver shall be required to give way to a pedestrian who, while on the footpath, indicates his intention to cross. It is urged that as a consequence a pedestrian will not be able to exercise his right to cross where there is a continuous stream of vehicular traffic but will have to wait indefinitely. Another innovation is the indicating of the crossing places (which are already marked on the ground) by yellow globes on poles about 7 feet high. Under the light of the lamps at night these globes show up. They were introduced because of difficulty in seeing the crossing places at night. They have been erected at distances of every few hundred yards in the London streets and though they must be useful are something of a disfigurement.

The Medical Training of South African Natives

The number of European physicians in South Africa is quite insufficient for the needs of the natives and the problem of training native physicians has arisen. The Witwaterstrand University of South Africa does not provide higher education for natives, and those willing and able to pay for it have to go overseas to British schools. But the university has laid down conditions under which it would be willing to train natives. In view of the strong prejudice of the European community, non-European students cannot be admitted to the existing medical classes but must be taught in separate classes. But it is laid down that the same training should be given and the same standard demanded as for European students. As the finances of the university could not support the additional burden entailed by the establishment of classes for non-European students, provision should be made by the government for the additional cost, including buildings and equipment as well as recurrent expenses.

French Urological Congress

The French Urologic Congress held its annual session in Paris in October. Dr. Chauvin of Marseilles, who had been appointed at the preceding annual meeting to read a paper on a specially chosen subject, gave an exhaustive review of inflammations of the testis and epididymis, exclusive of tuberculosis and syphilis. The first part of the paper took up the chronic forms of gonorrheal epididymitis, which are difficult to distinguish from other forms of chronic inflammatory enlargement of this structure, especially tuberculosis. The suppurating form of gonorrheal epididymitis is more frequently encountered. If the gonorrheal infection is latent, the differential diagnosis between an epididymitis due to the gonococcus from one due to tuberculosis or to the ordinary pyogenic organisms may be very difficult.

The second part of the report was devoted to the nonspecific forms of orchiepididymitis, which received little attention until toward the close of the last century. There is often a history of gonorrheal infection or of an injury. The organisms most commonly found are the colon bacillus and the various types of staphylococci, and they may be secondary to similar infections (generalized or localized) elsewhere in the body. Such localizations, however, more commonly involve the testis than the epididymis and hence the most probable mode of invasion of the latter structure is canalicular; that is, by way of the lumen of the vas deferens from infections of the prostate, seminal vesicles or a latent urethritis. The route of infection may also, but much less commonly, take place by way of the lymphatics of the vas, rarely by way of the veins. One sees clinically these nonspecific epididymitis cases in acute or nodular or suppurative or fibrous indurative form. The clinical picture resembles closely that due to the so-called specific forms. The *B. coli*

type involves the entire epididymis and hence may simulate a gonorrheal or tuberculous infection. Those due to the staphylococci occur in younger persons and are characterized by a less acute onset, less of a tendency to be bilateral but subject to frequent acute exacerbations.

The diagnosis of the various "nonspecific" forms depends on a search for other organisms than the gonococcus and tubercle bacillus. In the acute, the treatment is the same as in acute "specific" cases. In the chronic type, foci of infection must be eliminated in the urethra, prostate and seminal vesicles. Surgical intervention may be called for if fistulas persist or there are frequent acute exacerbations. Such operations as simple incision or removal of the epididymitis usually suffice. Castration is seldom indicated.

Pay Patients in Charity Hospitals

The medical profession of France has protested to the authorities regarding the large number of patients able to pay who receive free treatment in the dispensaries and wards of public hospitals. In the city of Paris alone there are about 35,000 beds available for the treatment of free patients, all under the direction of a central organization, the Assistance publique. The director of the latter has given instructions that in the future every applicant must sign a statement of his financial condition in order to exclude from free services those who are able to pay a physician in private practice. A recent writer in the *Concours médical* does not believe that such an exclusion of pay patients will ever be conscientiously carried out, because the budget of the free hospitals is in such a state that only about half of the money needed for maintenance is given by the local governments or received from legacies. Two solutions present themselves in the future. First, that only patients be received in the hospitals who cannot pay at all, and that additional structures be erected in connection with charity hospitals, where pay patients can be treated by the same medical staffs. This has been already carried out at Nancy, in eastern France. Second, that the entire medical personnel be given full time positions, with sufficiently adequate remuneration to enable them to forego the wish to treat private patients outside the hospital.

Madame Curie

In the September 22 issue of the *Presse médicale* appeared an account of the achievements of Madame Curie, by Professor Roussy, director of the Cancer Hospital of the University of Paris. Born in 1867 in Poland, Miss Sklodowska began her studies in France in 1894 and married Pierre Curie, a young physicist, the following year.

The first investigator to describe radioactivity of certain uranium salts and of the element itself was Henri Becquerel, in February 1896. Madame Curie, who was working independently in the laboratory of Professor Lippman, made her first communication in April 1898, before the Academy of Science, in which a new method, using electricity, was described, of demonstrating radioactivity in two minerals, pitchblende (uranium oxide) and chalcocite (double phosphate of copper and uranyl) as being much more marked than in uranium itself.

Pierre Curie associated himself with the work of Mme. Curie and on July 18, 1898, they announced the existence of a new radioactive substance contained in pitchblende. They suggested that the new metal be called polonium, in honor of Mme. Curie's natal country. Finally, Dec. 26, 1898, the discovery of radium was announced under the title "a new radioactive substance found in pitchblende." Three years later, Pierre Curie and Henri Becquerel read a paper on the physiologic action of radium emanations, and soon after some of the element was employed at one of the public hospitals of Paris in the treatment of cancer.

Mme. Curie and her husband received recognition in the form of the Nobel prize in physics and later in chemistry. Fellowship in the Academy of Science was bestowed on Mme. Curie after the death of her husband. Her daughter and son-in-law (Dr. Joliot) were associated with Mme. Curie in her research work and they will shortly announce the discovery of a method of preparing radium in the laboratory.

She continued her work until failing health compelled her to abandon it.

Burns of the Anterior Segment of the Eye

Prof. F. Terrien, at one of his clinics, called attention to certain features of burns by steam and by acid. To detect minute lesions of the cornea, which are invisible on examination even with the aid of a magnifying lens, Terrien employs a 1 per cent solution of fluorescein. After the instillation of one or two drops, the areas that have been denuded of their epithelial covering appear as greenish spots. In the first case this test revealed an extensive superficial burn of the cornea, which healed without loss of vision following the use of lavages, application of 1 per cent iodoform ointment and instillations of atropine. Burns due to steam can be considered as the least serious of all burns of the eye. In the second case, cement had been the cause of the burn. Although there had been corneal ulceration, treatment by hot applications and lavages had effected almost complete recovery.

In the fourth case the burn followed an explosion during the preparation of sulphuric acid and involved the eyelids, cornea and conjunctiva. In such cases the prognosis should be guarded so far as the cornea is concerned. Although apparently not involved primarily, it may become opaque as the result of secondary changes.

As an eye wash to be employed in large quantities, Terrien prefers a 1.4 per cent saline solution followed by a 1 per cent iodoform or mild silver protein salve to prevent the formation of a symblepharon. Burns due to lime are the most to be feared because here there are two factors, the heat generated by the lime and its chemical action.

Difficulties Encountered in Combating Venereal Diseases

The German Society for Combating Venereal Diseases instituted an inquiry among the physicians and hospitals concerning the management of venereal patients. The replies received indicate that in about half of the cases the treatment of persons of restricted means is inadequate. While a research is being made for the proper society to shoulder the burden of the expense, valuable days and weeks are often lost, particularly in the rural communities. In the case of persons who are insured indirectly through the head of the family, in which event the *krankenassen* bear only half of the expense for medicines, a delay often arises, if the patients are without means, before the other half of the cost of medicines can be guaranteed. In like cases an interruption of treatment may occur or the treatment may even be discontinued entirely. A similar situation arises when private insurance companies declare in their policies that no compensation will be paid for venereal diseases or when the granting of aid under such conditions is left to the discretion of the advisory board. Sometimes the public welfare department advance patients funds on condition that they shall be repaid within a certain time, and if the patient has any mortgageable property they may demand a mortgage to insure prompt repayment of such obligations. In some cases, parents are asked to guarantee the repayment of funds advanced for medical care of their children. As the examples just mentioned

show, hospitals and departments of public welfare do not preserve as they should the rights of privileged communication. It thus happens that nearly all women patients of a physician who records the actual diagnosis on the sickness certificate lose their positions. Many patients are deterred from applying for treatment, as they often must sit for hours in crowded policlinics beside morally depraved persons of both sexes. Another subject of frequent complaint is the unsatisfactory low fee allowed for treatments. A specialist often receives only from 12 to 20 cents for a treatment. A physician is held accountable if he demands higher fees than those established. In the replies to the questionnaire many physicians emphasized that the medicines needed for thorough treatment cost from two to four times the amount of the fees allowed. Many consultation centers state that practicing physicians refuse to cooperate with them. The reporting of negligent patients and the detection of sources of infection are carried out in a lax manner. Hence, Professor Spiethoff, of the University of Jena and the head of the German Society for the Combating of Venereal Diseases, has made a special appeal to the German physicians in which he emphasizes their duties in the matter of ferreting out sources of infection. The hospitals report that the number of hospital patients declines from year to year, not as a result of the decrease in gonorrhea but because of the difficulty encountered in being registered in the hospital under the auspices of the sick insurance institutions and public welfare offices. Hospital treatment may in various cases be prematurely canceled at the request of just such expense bearers. Many sick insurance companies grant, on principle, a period of hospitalization of only fourteen days. Patients with gonorrhea are sent to the hospital only in the event of serious complications. If the organizations defraying such expenses grant a period of hospitalization to a patient, they generally favor those hospitals with the lowest standards of treatment, where no special departments are to be found. Admittance was frequently refused to especially dangerous patients, such as prostitutes and concubines, on grounds of false economy. According to reports, it is believed that the hospital treatment of prostitutes may be done away with by enforcing sexual restraint on them. In the light of all this, it is of prime necessity that extensive treatment of venereal diseases be guaranteed by legal and organized measures. The state must find ways and means of forcing unapprehensive persons to fulfil their duties. Larger and broader demands must be made of the physicians' organizations.

It may be said with respect to prostitution that an artificially increased supply results in an artificially increased demand. In many large cities, attempts have been made again to confine prostitutes to designated houses and streets (which for years has been legally contested). The disadvantages of such confinement are not questioned. Only one tenth of the prostitutes are known to the authorities, and only a small number of these women can be provided for in brothels. Consequently this confinement has no influence on the disadvantages and dangers attendant on the widely scattered separate domicile of prostitutes. On the other hand, the streets frequented by the girls become centers of attraction for corruption, vice and perversion. Even the most conscientious medical examination is of no avail, because of frequent and promiscuous intercourse. Finally, such confinement is conducive to organized vice and prostitution. If prostitutes are segregated in secluded houses, if they choose their own dwelling or seek night quarters which to all appearances are inconspicuous, it may be regarded as a lesser evil. Despite quiet tolerance of such quarters in the streets frequented by prostitutes, the police are liable to interfere at any time.

Members of Krankenkassen and Number of Patients Treated

Recently a report was made on sickness insurance for the year 1933. Now the reports for the first six months of 1934 have been given out. The number of krankenkassen, as a result of merger, has notably diminished and the number of krankenkassen members has risen so that the tendencies displayed by the 1933 report have been continued. The membership increase in the federal insurance companies as in the

TABLE 1.—Increase in Membership of Federal Insurance Companies

End of Month	Number of Members (Thousands)		Increase per Thousand in 1934 - Corresponding Month of Preceding Year
	1933	1934	
January.	17,539	18,907	314
February	17,671	19,171	264
March.	17,040	19,444	273
April.	18,170	19,948	503
May.	18,516	20,158	210
June	18,616	20,163	5

auxiliary insurance organization, comprising both obligatorily insured and voluntarily insured persons, may be observed in table 1.

The slight increase in June is based on certain mathematical facts. The increase in insured from the beginning of 1934 to the end of June 1934 amounted to 1,570,000, and from the latter date to the beginning of 1933 amounted to 2,624,000. This increase is closely connected with the decrease in unemployment; here it must be kept in mind that not all the newly employed have also been obligatorily insured (e. g., because

TABLE 2.—Distribution of Members

Type of Organization	Number of Kassen in Each Organization	Approximate Number of Members (Thousands)	Number of Compulsory Insured, June 30, 1934 (Thousands)
Municipal krankenkassen	1,592	12,345	10,100
Rural krankenkassen	423	1,570	1,668
Factory krankenkassen.	3,354	3,044	2,697
Guild krankenkassen	726	545	476
Milner's krankenkassen	17	564	553
Total number of krankenkassen recognized by federal law.	6,412	18,374	15,496
Auxiliary (private) krankenkassen.	47	1,790	1,426
Total	6,459	20,164	16,922

TABLE 3.—Treatment During 1934

Month	Sick	Total	Percentage	
			Men	Women
January.	562,947	3	2.7	3.6
February	540,384	2.8	2.4	3.5
March.	488,656	2.5	2.2	3.2
April.	471,475	2.4	2	3
May.	465,553	2.3	2	2.9
June	480,828	2.4	2.1	3
Average	502,640	2.36	2.23	3.2

the salaries are too large to require this). Others have been able to evade compulsory insurance on similar grounds.

The distribution of members among the various krankenkassen and the distribution of compulsorily insured and voluntarily insured by June 30, 1934, is given in table 2.

Of 18,373,980 members of kassen recognized by federal law, June 30, 1934, 11,930,996 were men and 6,442,984 were women. The number of patients treated ("unemployable ill and puerperal women"), as measured by the sum total of insured for the year 1933, shows an average of 2.7; this means that 2.7 out of every 100 insured receive treatment. In table 3 is given the development in 1934

The already considerable decline of the number of sick demonstrated even further improvement in the year 1934. The numbers are generally higher for women than for men. The average for cases of absolute illness for the first six months of 1934 is likewise lower than the 1933 average. The municipal *krankenkassen* have the highest incidence of cases, in accordance with the size of their membership. The danger of illness is, as can be seen from the numbers, greatest in mining.

BUCHAREST

(From Our Regular Correspondent)

Oct. 1, 1934.

History of the Rumanian Faculty of Medicine

The Rumanian Medical Academy offered prizes for the best treatises on the history of the faculty of medicine in Rumania. Two were awarded prizes. It appears that the first medical school in Valachia, a province of Rumania, was founded ninety-three years ago. There were physicians practicing in Rumania prior to 1840, but they were foreigners: Italians, Germans and Greeks. There was among them also a Rumanian, Cretulescu, who felt the necessity of trained assistants who could help physicians in hygienic work, so he planned for a small surgical school at the Coltea Hospital. The hospital accepted his proposal and the surgical school was opened Sept. 21, 1841. There being no books, Cretulescu edited a book from which the apprentices could learn anatomy and physiology. Three hundred copies were distributed free among the students. March 3, 1843, Dr. Cretulescu appealed to the hospital board to place the whole Coltea Hospital at his disposal in order to establish a clinic for students. The board rejected this proposal, whereupon Cretulescu resigned and the school was taken over by Drs. Vartiade and Risdofer. The first graduates with diplomas left the school by the end of 1843. Then the school was closed, to be reopened May 2, 1852. The school was reopened in a much better condition as regards teachers and equipment, but it did not last longer than two months, for another school was established in the Mihai Voda palace, where the state archives were displaced.

About this time there came to Rumania a man of Italian descent, Carol Davila, but brought up and educated in France. He founded in the Mihai Voda palace the "small surgical school," and appealed to Prince Stirbey for permission to annex this school to the military hospital, which at this time was located in the building. The first professors in the school year of 1855-1856 were Davila, Poliuza, Barasch and Suhamel. In 1857, Davila had his pupils do anatomic dissections, of course secretly, in a barn, for such work was not compatible with the morals of the times. Dobrescu, a surgeon of Targoviste, narrated to many people, the following story, stating that he heard it from his father: A Gipsy woman came to the military hospital of Mihai Voda requesting the corpse of her son in order to bury him. By accident she stepped into the dissecting room, where Professor Davila was giving demonstrations on the cadaver of her son. She recognized the corpse and started such a shouting that the whole community became alarmed and Professor Davila and his pupils had to leave town to escape lynching. When the minister of war, Colonel Odobescu heard of this he immediately closed the medical school. Davila hastened to the French consul general, Beclard, and made a detailed report. The consul commanded Davila to reopen his school at once but henceforth to conduct it under the auspices of France. The patriotic Davila went to the prince and informed him what had happened. The prince considered the decree of the consul an offense and ordered Davila to open his medical school under the auspices of Rumania.

In 1858 the French ministry of public instruction issued a decree, which declared the Bucharest medical school to be equivalent to the French medical and pharmaceutical school and

at the same time the ministry permitted Bucharest senior students to complete their studies in France. The modest medical school became in 1869 a faculty of medicine. In 1860 the Mihai Voda palace proved inadequate and the faculty was moved to the military hospital in Stirbey Voda Street. In 1869 a building for the faculty was constructed in the boulevard, where it remained until 1901, when it was replaced by the modern well equipped Cotroceni building.

The Bucharest pathologic and bacteriologic institutes were opened, Aug. 12, 1887, the first under the management of Dr. Victor Babes, late lecturer to the Budapest University, for many years assistant to Professor Högyes. The object in establishing this institute was to conduct a campaign against epidemic diseases and rabies.

Another university with a medical faculty was established in 1890 in Jassy, the capital of Moldova, and with the annexation of Transylvania the country gained a third faculty of medicine, that of the University of Cluj, the capital of Transylvania. There is a fourth university in the country in Czernowitz, capital of Bucovina, without a faculty of medicine. It is the intention of the government shortly to erect here buildings for a faculty of medicine.

Pharmaceutic Firm Peddles Advertising Leaflets

One effect of the boycott of German goods has been that a large pharmaceutic firm descended from the pedestal of good taste and commenced house to house peddling with leaflets strongly recommending the use of a diuretic, one of its products. The firm is the Bayer firm, known as "Bayer-Meister-Lucius," I. G. Farbenfabrikenindustrie Aktiengesellschaft, Leverkusen a/Rh., Germany. The representative of the firm distributed leaflets (printed in German) to every house.

The Campaign in Bessarabia Against Typhus Exanthematicus

In Bessarabia, a province of Rumania, numerous cases of typhus exanthematicus have occurred in recent years, fortunately with but slight mortality. The government sent a special commission to Bessarabia to fight the scourge. Since March of this year, 245,000 persons have been deloused and individually disinfected, and 240 villages have been subjected to house to house disinfection. The special commission in one county (Lapusna) opened ten public baths. Formally, 90 per cent of the Bessarabian villages were infested with lice. The campaign has been so efficacious that last week only two cases of typhus exanthematicus occurred in the region of Chisenew.

MEXICO

(From Our Regular Correspondent)

Oct. 29, 1934.

Reorganization of Public Health Service

The members of the federal department of public health in Mexico have recently organized the so-called *unidad médico-sanitaria cooperativa*. The departments of inspection of immigrants, the campaign against prostitution, prevention of epidemics, the control and supervision of food, the water supply and the sewage services, which heretofore have been independent departments, now will cooperate as a unit under direct control of the department of public health of the capital of the state. The central department at the capital of the state has branches and connections with each given field in the state, so as to cover all cities, towns, villages, ports and ranches, and direct contact and advice from the central federal department of public health. The units are already functioning in Veracruz and Cuernavaca, are being organized in Nuevo León, Puebla, Guanajuato, Jalisco and Querétaro, and are being planned in Sonora, Sinaloa, Hidalgo and Morelos. A health unit in the department of irrigation, has been established in Anáhuac, an

important agricultural city in Nuevo León. Attention has also been given to the sanitary condition of places frequented by tourists, with an aim to prevent disease, especially various important places on the international highway that will connect Mexico City with the United States and which is now under construction. A sanitary brigade was recently sent to Tamazunchale to give smallpox and typhoid vaccination to the inhabitants and also to ascertain whether or not the conditions of the city meet the requirements for the establishment of a health unit in it. Tamazunchale is a city of importance on the international highway, in its passage through San Luis Potosí. The coordination of the health services represent preliminary steps for the establishment of the Mexican Plan Sexenal, according to which public health will greatly improve during the six year period of President Cardenas's administration, which will start December 1.

Modernization of Mexican Hospitals

The public, private, municipal and governmental hospitals in Mexico City have recently improved. The hospital Casa de la Beneficencia Española, a property of the Sociedad Española de Beneficencia, which was located on San Juan de Letrán Street, recently moved to a new location in the modern suburban town Chapultepec Heights. It now meets all the requirements that science demands of modern hospitals. The old site was donated to the city for the extension of a boulevard, now in construction, from the city to Los Alamos, a suburb.

The Hospital Francés, a hospital for private patients, has doubled its number of beds and has a new chapel for religious services for patients and their relatives. The new furniture and equipment are of the best type.

The Mexican Red Cross Emergency Hospital, for the care of persons injured in accidents, has moved to its own new building at the corner of Monterrey and Durango streets. The new building, the furniture and equipment are modern.

The government of the city supports also a department with services for the immediate treatment of persons injured in accidents and other emergencies. This department is known as the Hospital of Emergencies of the Green Cross. Up to recently its functions were limited to the performance of emergency operations and the administration of first aid. The Hospital of Emergencies of the Green Cross recently was radically renovated by the establishment of a new central station and of small outlying stations covering all parts of the city. Each station has a suitable building with waiting and resting rooms and medical and surgical wards, also an ambulance service, and physicians and nurses who work in turns so as to provide twenty-four hour service. These improvements have resulted in saving the lives of many of the injured.

Reunion of Texas Internists in Mexico City

The members of the Texas Club of Internal Medicine, under the chairmanship of Dr. Kopescki, held their annual reunion in Mexico City, September 17-21. The program was organized by the members of the Sociedad Mexicana de Medicina Interna, who received their Texas colleagues as their hosts. The papers presented by members of the Sociedad Mexicana de Medicina Interna were written in English and discussed by the members of both societies. Some of the topics discussed were cancer of the esophagus, the clinical and roentgen picture of silicosis in Mexico, the treatment of tuberculosis in Mexico, pseudocancer of amebic origin, the first book on physiology published in America, biliary lithiasis, a comparative study of cardiac telerradiography and orthodiagraphy, lymphoid leukemia, immune serum in exanthematous typhus, a new method of pyretotherapy, schizophrenia and physical therapy. The program included visits to the Hospital General, Hospital Juárez, Manicomio General of Mixcoac, the Instituto de Higiene of Popotla, the

School of Medicine, the public health department and some other places of medical interest. Scientific meetings were held at the Hospital General, various well equipped departments of which, especially those devoted to medical education, were shown to the visitors. The equipment of this hospital for the teaching of cardiology, with apparatus for collective auscultation, and that for the teaching of urology, deserve especial mention. The Texas physicians were invited to a special meeting of the Sociedad Mexicana de Medicina Interna and to a meeting of the Academia Nacional de Medicina of Mexico, held in their respective headquarters, in honor of the visitors. A banquet presented by the Mexican physicians to the Americans, which was characterized by great cordiality, ended the reunion, during which the fraternal relations and better understanding of the American and Mexican physicians were emphasized. English was spoken in all receptions given to the visitors.

Meeting of Surgeons

Mexican surgeons will meet in a general reunion, November 18-24, at the Hospital Juárez, a surgical center of renown. The reunion was organized by the members of the Sociedad de Cirugía del Hospital Juárez, under the auspices of the members of the Office of Public Welfare of the Federal District. Some departments of the hospital, which have been recently improved or remodeled with the resources of the public welfare department, will open with inaugural ceremonies during the days of the reunion. The scientific program will be of interest. There will be an exposition of surgical instruments and apparatus made by Mexican physicians and surgeons.

Marriages

SYLVESTER W. RENNIE, Wilmington, Del., to Miss Margaret Carolyn Valentine of St. Louis in New York, September 29.

BERKELEY HANCOCK MARTIN to Miss Elizabeth Sydnor McCraw, both of Richmond, Va., September 29.

EUGENE BYRON GLENN, Asheville, N. C., to Miss Virginia Grace Mason of Birmingham, Ala., November 3.

THOMAS EDGAR PAINTER, Williamsburg, Va., to Miss Frances Angelina Curtis of Liberty, N. C., October 15.

DUNCAN SHAW OWEN, Fayetteville, N. C., to Miss Mary Gwyn Hickerson of Lenoir, in October.

JOSEPH LINN HETZEL to Miss Margaret Spencer de Lancey, both of Waterbury, Conn., October 12.

CHARLES DEXTER LUFKIN, Northfield, Minn., to Miss Ann E. Gwynne of Windber, Pa., recently.

CHARLES LORRAINE CABELL to Miss Elizabeth DeVega Danford, both of Richmond, Va., July 28.

JOSEPH STANLEY FAULKNER, Hazard, Ky., to Miss May Drew Hendren of Danville, recently.

WILLIAM LOUIS WOOLFOLK, Owensboro, Ky., to Miss Julia Porter of Paris, Tenn., October 20.

CLARENCE S. THOMAS to Miss Mary Elizabeth Keller, both of Nashville, Tenn., November 3.

ARTHUR E. MORGAN to Miss Frances Mauney, both of Lincolnton, N. C., October 25.

DAVID HENRY POER to Miss Margaret Underwood, both of Atlanta, Ga., October 30.

JOHN EDWARD SHORT to Miss Catherine Julie Connelly, both of Los Angeles, October 9.

ALONZO NEWTON BAKER to Miss Esther McLaren, both of Marion, Ill., October 25.

GEORGE HAMMOND to Miss Marian Davis, both of Ann Arbor, Mich., October 1.

EMANUEL J. RICHTER to Miss Amy Maret, both of New York, in August.

JAMES LEE PITTMAN to Miss Clare Jones, both of Atlanta, Ga., October 16.

BOOKER LEE to Miss Nellie Estelle Lindsay, both of Pulaski, Va., in June.

Deaths

Wendell Christopher Phillips * President of the American Medical Association in 1926-1927, died at his home in New York, November 16, aged 77. Dr. Phillips was born in Hammond, N. Y., June 9, 1857. After attendance at Potsdam (N. Y.) Normal School, 1876-1879, he entered the University of the City of New York Medical Department, receiving his degree in 1882. Specializing in diseases of the ear, nose and throat, he became consulting aural surgeon to the New York Post-Graduate and Flushing hospitals and aural surgeon to the Manhattan Eye and Ear Hospital. He served as a member of the House of Delegates of the American Medical Association for six years, 1912-1917, and as chairman of the Section on Laryngology, Otology and Rhinology, 1923-1924. He was a member of the Board of Trustees from 1917 to 1924 and was for several years a member of the Executive Committee and also chairman of the board. Dr. Phillips became president-elect of the Association in 1925. He was a member of the American and of the New York otolaryngologic societies, and was president of the American Laryngological, Rhinological and Otological Society in 1907; he was also a member of the New York Academy of Medicine and in 1912 was president of the Medical Society of the State of New York. In 1919 Dr. Phillips helped organize the American Federation of Organizations for the Hard of Hearing and in 1920 became its first president. He was a fellow of the American College of Surgeons and in 1904 president of the New York County Medical Society. Dr. Phillips contributed much to the subject of otology in medical literature, including a textbook on "Diseases of the Ear, Nose and Throat, Medical and Surgical," which is used in many medical colleges. He was widely known in the medical profession for his high ideals, his enthusiastic leadership, his warm congeniality and his unwavering support of organized medicine.

William Chittenden Lusk, New York; Bellevue Hospital Medical College, New York, 1893; member of the Medical Society of the State of New York; emeritus professor of clinical surgery, New York University, University and Bellevue Hospital Medical College; fellow of the American College of Surgeons; consulting surgeon to the Bellevue, St. Vincent's and Manhattan State hospitals; aged 66; died, October 24, of Parkinson's disease.

Mathew Nelson Voldeng * Woodward, Iowa; College of Physicians and Surgeons of Chicago, 1887; member of the House of Delegates of the American Medical Association, 1912-1920 and in 1924; member and past president of the Iowa State Medical Society; member of the American Psychiatric Association; professor of pathology, 1897-1898, and of neurology and psychiatry, 1899-1902, Drake University Medical Department, Des Moines; superintendent of the Cherokee (Iowa) State Hospital, 1902-1915; medical superintendent of the Hospital for Epileptics and School for Feeble-minded; aged 71; died, October 21.

Henry John Wynkoop * Bath, N. Y.; New York University Medical College, 1898; Cornell University Medical College, New York, 1899; fellow of the American College of Surgeons; on the staffs of the Bath Hospital, Pleasant Valley

Sanatorium and the Veterans' Administration Facility; aged 58; died, October 16, of coronary thrombosis.

John Alexander Cochran * Brooklyn; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1881; veteran of the Spanish-American and World wars; for many years medical inspector in the health department; aged 74; died, November 1, in the Brooklyn Hospital, of heart disease.

William Jones Wallace * Oklahoma City; University of the South Medical Department, Sewanee, Tenn., 1901; professor of genito-urinary diseases and syphilology, University of Oklahoma School of Medicine; member of the American Urological Association and fellow of the American College of Surgeons; on the staff of the State University Hospital; aged 61; died, September 19, of multiple myeloma.

Walter Booth Hotchkiss, Fort Steilacoom, Wash.; Chicago Homeopathic Medical College, 1904; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1906; on the staff of the Western State Hospital; aged 64; died, October 13, of lobar pneumonia and cerebral embolism.

Newton Harvey Lindsey * Pauls Valley, Okla.; Memphis (Tenn.) Hospital Medical College, 1898; past president and secretary of the Garvin County Medical Society; fellow of the American College of Surgeons; part owner of the Lindsey-Johnson Hospital; aged 64; died, October 25, of coronary occlusion.

Charles James Howard * Rutland Heights, Mass.; Columbia University College of Physicians and Surgeons, New York, 1897; member of the Colorado State Medical Society; for many years on the staff of the Veterans' Administration facility; aged 61; died, October 25, of heart disease and bronchial asthma.

George Rufus Drake * Plymouth, Pa.; University of Pennsylvania School of Medicine, Philadelphia, 1906; past president of the Luzerne County Medical Society; aged 55; on the staff of the Wilkes-Barre (Pa.) General Hospital, where he died, October 15, following an operation for appendicitis.

Nelson Henry Beemer, Toronto, Ont., Canada; University of Toronto Faculty of

Medicine, 1874; formerly professor of mental diseases at his alma mater; member of the American Psychiatric Association; for many years superintendent of the Ontario Hospital, Mimico; aged 81; died, September 23.

Archie W. Herrick * Bay City, Mich.; Saginaw (Mich.) Valley Medical College, 1901; past president of the Bay County Medical Society; at one time health officer of Bay City; on the staff of the Mercy Hospital; aged 66; died, October 22, of gallbladder disease and angina pectoris.

James David Hobson * Missoula, Mont.; Cleveland College of Physicians and Surgeons, Medical Department Ohio Wesleyan University, 1910; served during the World War; secretary of the Western Montana Medical Society; aged 50; died, October 13, of pneumonia.

Theodore Hamilton Weagley * Marion, Pa.; College of Physicians and Surgeons, Baltimore, 1882; past president of the Franklin County Medical Society; on the staff of the Chambersburg (Pa.) Hospital; aged 72; died suddenly, September 24, of angina pectoris.

WENDELL CHRISTOPHER PHILLIPS, M.D.
1857-1934

Sophie Bade Scheel, Passaic, N. J.; New York Medical College and Hospital for Women, New York, 1901; formerly professor of the practice of medicine at her alma mater; aged 75; died, October 10, at her home in Rosemawr, of cerebral embolism and arteriosclerosis.

Benjamin George Moran @ Nashua, N. H.; University of the City of New York Medical Department, 1891; fellow of the American College of Surgeons; aged 64; on the staffs of the Nashua Memorial Hospital and St. Joseph's Hospital, where he died, September 26.

James Wesley McClendon, Supply, Okla.; Kentucky School of Medicine, Louisville, 1894; member of the Oklahoma State Medical Association; medical superintendent of the Western Oklahoma Hospital; aged 66; died, October 2, at his home in McAlester.

George Wells Fitz, Peconic, N. Y.; Harvard University Medical School, Boston, 1891; aged 74; died, October 28, in the Eastern Long Island Hospital, Greenport, of injuries received when the automobile in which he was driving was struck by a train.

Frank Leavens Walton, Muskogee, Okla.; Louisville (Ky.) Medical College, 1890; member of the Oklahoma State Medical Association; formerly member of the state legislature; at one time county health officer; aged 66; died, October 6, of pernicious anemia.

William Patrick O'Ready @ Claymont, Del.; Georgetown University School of Medicine, Washington, D. C., 1927; on the staffs of the Wilmington General, Delaware and St. Francis hospitals, Wilmington; aged 38; died suddenly, October 9, of heart disease.

James Barbee O'Bannon @ Mount Carmel, Ky.; University of Louisville School of Medicine, 1892; secretary of the Fleming County Medical Society; for many years county health officer; aged 70; died, October 23, of sarcoma of the hip and sigmoid.

William Constantine Abaly, Madison, Wis.; College of Physicians and Surgeons of Chicago, 1886; aged 71; died, October 12, in the Wisconsin State Hospital, Mendota, of cerebral hemorrhage, bronchopneumonia and arteriosclerosis.

Henry J. Harnisch @ Flagstaff, Ariz.; St. Louis Medical College, 1881; member of the Missouri State Medical Association; for many years on the staff of the Lutheran Hospital, St. Louis; aged 76; died, October 23, of heart disease.

Herbert Rogers Wardlaw @ San Angelo, Texas; University of Texas School of Medicine, Galveston, 1907; aged 52; on the staff of the Shannon West Texas Memorial Hospital, where he died suddenly, October 11, of heart disease.

Joseph Isaac Bluestone, Brooklyn; University of the City of New York Medical Department, 1890; for many years on the staff of the Beth Israel Hospital; aged 74; died, November 2, of cerebral thrombosis and bronchopneumonia.

Homer Elbert McGhee, Kansas City, Mo.; University Medical College of Kansas City, 1912; member of the Missouri State Medical Association; served during the World War; aged 49; died, October 14, of pneumonia.

Thomas Hayden Ensor, Omaha; St. Louis Medical College, 1880; formerly mayor of South Omaha; aged 76; died, October 13, in the Providence Hospital, Detroit, of chronic cholecystitis and coronary thrombosis.

Leonard Daniel McCarthy, Perry Point, Md.; George Washington University School of Medicine, Washington, D. C., 1929; aged 35; on the staff of the Veterans' Administration Facility, where he died, October 11.

Philip H. Comas, Baxley, Ga.; University of Maryland School of Medicine, Baltimore, 1882; member of the state legislature and formerly state senator; aged 73; was found dead, October 19, of heart disease.

J. W. Crewdson, Louisiana, Mo.; University of Louisville (Ky.) School of Medicine, 1880; member of the Missouri State Medical Association; mayor of Louisiana; aged 75; died, September 29, of chronic nephritis.

John Walter Crews, Atwood, Okla. (registered in Oklahoma by the state board of health, under the Act of 1908); member of the Oklahoma State Medical Association; aged 69; died, in October, of pneumonia.

Wilbur Ervin Wendt, Beaver Dam, Wis.; University of Wisconsin Medical School, Madison, 1934; aged 23; died, October 2, in the Wisconsin General Hospital, Madison, of chronic nephritis and uremia.

John Aloysius Hickey, Winthrop, Mass.; Harvard University Medical School, Boston, 1896; aged 68; died, October 26, of arteriosclerosis, chronic endocarditis, acute nephritis and bronchopneumonia.

Margaretta Rulison Riegel Valentine, New York; Syracuse University College of Medicine, 1912; aged 50; died, October 9, in the Holy Name Hospital, Teaneck, N. J., of intestinal obstruction.

Louis Frederick Arensberg, Arensberg, Pa.; University of Michigan Medical School, Ann Arbor, 1867; Civil War veteran; formerly member of the state legislature; aged 91; died, September 21.

Margaret Billingsley Mills, Ottumwa, Iowa; Northwestern University Woman's Medical School, Chicago, 1893; formerly city health officer; aged 72; died, September 30, in the Ottumwa Hospital.

Otis Wood Allison @ Danville, Ill.; Rush Medical College, Chicago, 1905; aged 57; on the staff of the Lake View Hospital, where he died, October 28, of aplastic anemia and acute myeloid leukemia.

William Stephen Lynch, Buffalo; University of Buffalo School of Medicine, 1904; served during the World War; aged 54; died, November 1, in the Sisters Hospital, of cardiovascular disease.

William T. Hamilton, Athens, Ga.; Georgia College of Eclectic Medicine and Surgery, Atlanta, 1905; aged 67; died, October 20, in the General Hospital, of nephritis, arteriosclerosis and uremia.

Herbert Clift Brown @ Brookfield, N. Y.; Syracuse University College of Medicine, 1881; for many years health officer of Brookfield; aged 77; died, November 1, of cerebral hemorrhage.

Jackson M. Nunez, Swainsboro, Ga.; University of Georgia Medical Department, Augusta, 1886; member of the Medical Association of Georgia; aged 75; died, in October, of cerebral hemorrhage.

Rossie R. Walker, Laurens, S. C.; University of Louisville (Ky.) School of Medicine, 1908; member of the South Carolina Medical Association; aged 51; died, October 16, of coronary thrombosis.

John Felton Taylor, San Francisco; College of Physicians and Surgeons of San Francisco, 1918; aged 42; died, September 19, in St. Joseph's Hospital, of carcinoma of the urethra.

Leo Charles Kinsella, Chicago; Chicago Medical School, 1923; member of the Illinois State Medical Society; aged 52; was found dead, October 24, of carbon monoxide poisoning.

Albert Brandon Davenport, Columbus, Ohio; Columbus Medical College, 1890; aged 72; died, October 18, in St. Anthony's Hospital, of arteriosclerosis and bronchopneumonia.

Edward Orton Willoughby, Dayton, Ohio; Cleveland Homeopathic Medical College, 1901; formerly county coroner; aged 60; died suddenly, October 15, of coronary thrombosis.

Robert William Oakley, Moline, Ill.; Northwestern University Medical School, Chicago, 1902; served during the World War; aged 59; died, October 18, in the Moline City Hospital.

William Edgar Vaden, Chattanooga, Tenn.; Vanderbilt University School of Medicine, Nashville, 1899; member of the Tennessee State Medical Association; aged 62; died, October 22.

James Martin Joshua Luke @ Miami, Fla.; University of Louisville (Ky.) School of Medicine, 1913; served during the World War; aged 45; died, October 9, of angina pectoris.

Caleb Huntington Atwater, Wallingford, Conn.; College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1871; aged 91; died, October 28.

Clarence Burdette Wean, Andover, Ohio; Western Reserve University Medical Department, Cleveland, 1901; aged 57; died suddenly, October 14, of angina pectoris.

Edwin Barney Herring, Dundee, Miss.; Vanderbilt University School of Medicine, Nashville, Tenn., 1888; aged 70; died, October 20, of a self inflicted bullet wound.

William Thomas Greene, Bumpus Mills, Tenn.; University of Tennessee Medical Department, Nashville, 1894; aged 75; died, October 9, of carcinoma of the prostate.

Edward Everett Kenyon, South Kingstown, R. I.; University of Vermont College of Medicine, Burlington, 1880; aged 74; died, September 22, of angina pectoris.

Joseph Albert Lowe, Pleasant Prairie, Wis.; Bennett College of Eclectic Medicine and Surgery, Chicago, 1902; aged 64; died suddenly, October 16, of angina pectoris.

William Rupert Esdale, Ottawa, Ont., Canada; McGill University Faculty of Medicine, Montreal, Que., 1926; aged 33; died, October 17, of meningitis.

John Brodie Head, Gallatin, Tenn.; University of Nashville Medical Department, 1869; aged 85; died, September 29.

Bureau of Investigation

KELPE'KOE

The Commercial Possibilities of Crude Ore as a "Patent Medicine"

"Kelpe'koe" is a later name given to a product known earlier as "Pacific Health Ore." In the latter part of 1931 it was reported that a Mr. Ben Sweetland, president of the Sweetland Advertising, Inc., of New York City, had become interested in the financial possibilities of selling this brand of crushed rock as a "patent medicine." As a result of this interest, Kelpe'koe, Inc., was brought into existence.

The company was incorporated Dec. 15, 1931, under the state laws of Arizona, with 5,000,000 shares of common stock at a par value of 10 cents a share to be sold to the public at 20 cents a share. Of these 5,000,000 shares, 1,103,429 shares were issued to the Pacific Health Ore Company for all the assets of that company, including perpetual lease on the deposit of shale and a contract to purchase the property outright and the exclusive distribution of the ore. One half of the 5,000,000 shares, or 2,500,000 shares, were "issued or to be issued for bonuses, services, etc." On Oct. 30, 1934, the Corporation Commission of the State of Arizona reported that since 1932 Kelpe'koe, Inc., had failed to file reports or pay its annual registration fee as required by law. It appears, therefore, that the company is "legally dead" under the laws of Arizona.

THE STOCK-SELLING SCHEMES

In January 1932, promotional letters were sent out by W. L. Coe & Company of Seattle, setting forth the alleged commercial possibilities in the sale of the product Kelpe'koe. W. L. Coe & Company have been described as "a small concern doing a mail-order and telephone business in mining stocks." It is of incidental interest to learn that the broker's license of W. L. Coe & Company is said to have been canceled in June 1932. The promotional literature sent out by the Coe concern enlarged on the marvelous financial possibilities in the sale of blue shale at \$4.85 a pound or \$9,700 a ton!

In the stock prospectus sent out at this time, it was stated that Kelpe'koe, Inc., was located at Salem, Ore., and had a capitalization of \$500,000, "all common and non-assessable." The following were given as the officers and directors of the company: Ben Sweetland, D. R. Riegel, P. D. Ott, R. H. Pfeffer, Bailie N. Savage.

Further, according to the prospectus, the company was sending out daily 10,000 letters advertising Kelpe'koe, from which it was claimed they received 600 to 800 orders a day. From this the promoters estimated that this should net the company a profit of from \$50,000 to \$100,000 a month. At that time, according to the prospectus, shares in Kelpe'koe, Inc., were being offered, not at twenty cents, but at thirty cents each.

As already stated, the first prospectus was sent out in January 1932 by W. L. Coe & Company. In the same month another series of Kelpe'koe stock-selling letters was sent out by the American Exploration Company of Spokane, Wash. These letters were signed B. Saunders, secretary-treasurer of the American Exploration Company. A follow-up on this promotional letter came on the stationery of R. H. Pfeffer, whose letterhead described him as president of the American Exploration Company. Mr. Pfeffer, it will be noted, was one of the men listed as an officer and director of Kelpe'koe.

The letters from the American Exploration Company were typical of dubious promotional schemes. They stressed the instances of other companies that had started as midgets and had become financial giants; they reminded the prospective purchaser "of the millions of dollars that are made annually in 'patent medicines'"; they estimated that Kelpe'koe stock would have "an earning power of from 12 cents to 24 cents per share and a potential market value of at least \$1 to \$2 a share the first year."

The letters further impressed the prospective buyer with "the fact that there are only a very few shares of Kelpe'koe stock available for distribution." There was enclosed with the letter a "\$10 option on 250 shares of stock in Kelpe'koe, Inc." and the recipient was urged to send \$10 for this option cer-

tificate. He was told that if he sent in the \$10 he would be under no obligation to purchase the additional 200 shares, but would receive 50 shares for the \$10. Those who were thus approached but failed to send in the \$10 received some days later a letter from Mr. R. H. Pfeffer. This letter was even more appealing than the earlier one, and the recipient was urged to send in \$10 in full payment for the option certificate already referred to and any time within thirty days from the date of Mr. Pfeffer's letter the \$10 would be returned if the purchaser was not satisfied.

A later letter from Mr. Pfeffer in February 1932 enclosed three certificates of stock (one for 100 shares and two for 200 shares each) in Kelpe'koe, Inc., issued in the name of the person to whom the letter was written and to whom was given the "privilege of purchasing from 100 to 500 shares at 20 cents a share"—provided the remittance was mailed not later than twelve days following the receipt of the letter. The stock certificates were very imposing, printed in green and black, and bore what purported to be serial numbers imprinted in red.

Ferric	Fe ₂ (SO ₄) ₃828
Organic Matter		2.500

Respectfully submitted,
MEMBERS OF AMERICAN SOCIETY FOR TESTING MATERIALS
BOWSER-MORNER TESTING LABORATORY

Photographic facsimile of an analysis sent out when Kelpe'koe was being promoted as a stock selling proposition. The earlier name for Kelpe'koe was Pacific Health Ore. Note that the ingredients are shown to be combined in inorganic and not organic form, as claimed by this concern. Note, too, that the only ingredients present in substantial amounts are aluminum sulphate and iron (ferrous) sulphate—green vitriol. No cobalt was reported found!

The American Exploration Company is said to have sold over a million shares of Kelpe'koe, Inc., stock, from the sale of which it received over \$8,000 and Kelpe'koe, Inc., over \$24,000. Presumably Mr. Pfeffer, as president of the former company and as an officer and director of the latter, participated in the profits of both. The National Better Business Bureau reports that in February 1932 the Pennsylvania Securities Commission served notice on the American Exploration Company to cease offering stock in Kelpe'koe, Inc., in Pennsylvania. The American Exploration Company, like many other concerns with which Mr. Pfeffer has at times been connected, seems no longer to be in existence.

THE PRESENT CONCERN

So much for the earlier promotional activities of Kelpe'koe. Today the company is said to have the following personnel:

Pheron D. Ott, president; D. R. Riegel, vice president, and Bailie N. Savage, secretary, treasurer and manager; the directors of the company are also its officers. Ben J. Sweetland, its first president, withdrew in 1932; R. H. Pfeffer, his successor, withdrew in 1933.

Just as the earlier personnel included no physicians or pharmacists but did include advertising men and stock promoters, so the present officers and directors are without medical or pharmaceutical qualifications. Mr. Ott, the president, is said to have been engaged previously in the gasoline service-station business and later to have been an employee of a grocery concern. Mr. Riegel, its vice president, is said to be,

Photographic reproduction (greatly reduced) of one of the Stock Certificates for 200 shares that were sent out by Mr. Pfeffer, former president of the Kelpe'koe concern, when he was attempting to promote the sale of stock in his company.

and to have been for many years, in the automobile agency business. Mr. Savage, it appears, was a bank clerk prior to becoming secretary, treasurer and manager of Kelpe'koe, Inc.

It is a curious and possibly significant fact that, although Kelpe'koe, Inc., has been doing business for three years in the state of Washington and has sent and is sending out from Seattle quantities of advertising matter all over the United States, the secretary of state at Olympia, Wash., notified the Bureau of Investigation, in reply to a request, that the department of state was "unable to locate Kelpe'koe, Inc., on the records of this office, either as a foreign or domestic corporation." From this it would seem that Kelpe'koe, Inc., as a corporation is legally dead in Arizona, where it was first incorporated, and is legally unknown in the state of Washington, where it has its quackery headquarters. It would appear from the Revised Statutes of Washington that as Kelpe'koe, Inc., as a foreign corporation has failed to pay its annual license fee and to file and record its certified copy of the charter, as well as the appointment of its agents, it is subject to certain penalties, as provided by the state law.

WHAT IS KELPE'KOE?

As part of the advertising "come-on" in the W. L. Coe & Company prospectus, there was reproduced what purported to be an analysis of the product, made by the Bowser-Morner Testing Laboratories of Dayton, Ohio. This analysis is reproduced in miniature with this article. It will be seen from this analysis that the essential substances in Kelpe'koe are aluminum sulphate and ferrous sulphate (green vitriol). The other ingredients may be disregarded because of their minute amounts. The method of using this preparation will be referred to later.

In the circular letter that accompanied the reproduction of the Bowser-Morner Testing Laboratories' report, it was stated:

"The laboratory report was startling, indeed. The ore was found to contain fifteen different minerals—the very elements contained in the human body. And furthermore, tests revealed that these minerals were in organic form . . ."

This wording is typical of the loose use of scientific terms common to nostrum exploiters. The body does *not* contain fifteen "minerals," although it does contain more than that number of "elements." Even the analysis referred to, it will be noted, discloses *not* fifteen elements, but only thirteen, and specifically declares that these elements were combined in the *inorganic* form and not in the organic form, as the promoters' letter said.

As originally exploited, the product was put out as a frank cure-all, and it was claimed that "sensational results have been obtained with Pacific Health Ore in the following conditions: Diabetes, Kidney and Liver Disorders, Gas and Ulcers of the Stomach, Hemorrhoids, Colitis, Eczema and Skin Trouble, Rheumatism, Goiter, Tonsillitis, Infections, Female Disorders, Etc." After the change of name from Pacific Health Ore to Kelpe'koe, the therapeutic claims became more specific. And the price was nearly doubled! As Pacific Health Ore it was sold for \$2.50 a pound; as Kelpe'koe it was sold for \$4.85 a pound. "Never give the sucker a break!"

One of the specific claims for Kelpe'koe was that it was a "rejuvenator"—and was "the most effective natural tonic and body builder for men and women ever discovered in the history of medical research." One letter sent out by Kelpe'koe, Inc., opened with this paragraph:

"Rejuvenate! What a word to conjure with! How vividly it recalls Goethe's immortal poem, Faust—the most dramatic story of rejuvenation ever written."

Then in the four-page broadside, the *Kelpe'koe News*, under the heading: "Men—Old Age Deferred—Youthful Glands":

"Owing to the glandular rejuvenation of Kelpe'koe, it is a most potent factor in renewing strength and restoring vigor and vitality."

Kelpe'koe is sold today in two forms—"Natural" and "Capsules." Kelpe'koe "natural" comes in a carton of four quarter-pound packages of the crushed ore. The instructions for preparing it as a medicine are to empty one of the quarter-pound packages into a bottle and pour over it a pint of hot water. This is to be allowed to stand for twenty-four hours, shaking occasionally and then straining off the supernatant liquid, which is to be taken one or two teaspoonfuls at a time, diluted in a glass of water. "Kelpe'koe Capsules" contain a dirty-white powder said to be produced by the evaporation of strong solutions of "Kelpe'koe Natural."

The Kelpe'koe concern's recent advertising has been devoted to the thesis that solutions of this crushed ore will cure diabetes. The outfit even has the effrontery to circularize physicians, to whom it particularly recommends the "Capsules."

A year after the first stock-selling letter was sent out with the laboratory report, the Kelpe'koe concern added *cobalt* to the list of the alleged ingredients of its nostrum. In this connection the following facts are of interest: The names of three laboratories have been used in the advertising of Kelpe'koe: Bowser-Morner Testing Laboratories of Dayton, Ohio, already referred to; Arthur D. Little, Inc., Cambridge, Mass., and A. L. Knisely Chemical Laboratories, Seattle. (Mr. Knisely is described by Kelpe'koe as "former Chief Chemist for the U. S. Pure Food and Drug Administration at Seattle.")

★ USERS OF INSULIN

have obtained some measure of relief and scientific research has now developed a treatment of more permanent benefit, to be used with or without Insulin. More liberal diet permitted. Write Kalpokoe Corporation, Seattle, Washington.

Most of the Kelpe'koe advertising seems to be of the "direct-by-mail" type. Some advertising has been done in magazines of the cheaper type.

The implication in the Kelpe'koe advertising is that all these analysts found "cobalt" among other ingredients in the ore. A glance at the Bowser-Morner report shows that that laboratory did not mention cobalt as an ingredient. Arthur D. Little, Inc., reports that they also did not report on finding cobalt—in fact, they were given a list of the Kelpe'koe ingredients and asked to determine whether the material submitted corresponded with the list given—and cobalt was not in the list!

But apparently it was decided that cobalt would make good advertising material when the Kelpe'koe concern had unearthed an old and obscure newspaper clipping that fitted in with the plan to exploit the nostrum as a cure for diabetes. It appears that a French physician, Bertrand, claimed in 1926 that the potency of insulin for the elimination of dextrose in the blood would be increased when the reaction takes place in the pres-

ence of infinitesimal amounts of nickel and cobalt. The Kelpe'koe concern is sending out today (1934) a photographic reproduction of a news item reporting the meeting of the American Chemical Society Institute at Northwestern University at Evanston, Ill. This item referred to the mention—entirely incidental—of Bertrand's theory. The Kelpe'koe letter that accompanies the reproduction of the news item states that this is a "report which bids fair to revolutionize all former ideas as to the treatment of diabetes." The news item bears a date line of August 1 but no year. Recipients naturally infer that it means August 1934; actually the meeting was held six years ago—in 1928!

The facts are that, although eight years have elapsed since Bertrand first made his report, his theory has found no general acceptance by scientific medicine.

The perniciousness, not to say wickedness, of exploiting this crude ore as a rational treatment for diabetes, and the implied claim that by using it, it will be possible to abandon the use of insulin, is, of course, not as obvious to the diabetic as it is to every physician. Not that the Kelpe'koe concern is crude enough to state that its product is a specific or a cure for diabetes. "Patent medicine" concerns in 1934 don't work that way. Kelpe'koe, Inc., in fact, specifically states that the product is "not offered to you as a medicine, specific or cure,"—and then goes on to publish testimonials alleged to be from diabetics who claim to have been cured! As has already been stated, on the admission of the exploiters themselves, the person who takes Kelpe'koe is getting, for all practical purposes, merely a solution of alum and iron sulphate.

In due time, undoubtedly, the overworked branch of the federal authorities that looks into the misuse of the mails by quacks and others will get around to Kelpe'koe, Inc. This, too, in spite of the fact that the Kelpe'koe concern in its advertising states that "Among the users and boosters for Kelpe'koe are included . . . Post Office inspectors. . . ."

FLAT FEES IN INDUSTRIAL MEDICAL SERVICE

To the Editor:—May I call your attention to the following action taken by the Lumbermens Mutual Casualty Company, 4750 Sheridan Road, Chicago:

Recently I received many communications from members of the Chicago Society of Industrial Medicine and Surgery stating that they had been sent a flat fee of \$4.50 on all bills they had rendered to the Lumbermens Mutual Casualty Company for medical services to injured employees coming under the Illinois workmen's compensation act when these employees lost no time from work. This \$4.50 was to remunerate them for their services regardless of the size of their bill, in some instances the bill running well above \$20 but rarely as low as \$4.50. This action was taken without consulting the doctors in question, and on making inquiry of Mr. Howe, second vice president and general claim manager, they were informed that, from a study the Lumbermens Mutual Casualty Company had made, the bill for medical and surgical services should not average over \$4.50.

At a special meeting of the Chicago Society of Industrial Medicine and Surgery, called for the purpose of discussing this particular question, the unanimous decision was that the secretary be instructed to inform Mr. Howe, second vice president and general claim manager of the Lumbermens Mutual Casualty Company, that the doctors specializing in industrial medicine and surgery were unanimously opposed to a flat fee proposition and that they were unanimously rejecting this proposition of \$4.50. The secretary notified Mr. Howe of the action of the society but he did not as much as acknowledge the letter, and I understand that, regardless of the protest, he

is proceeding with this plan, apparently hoping that at this time of financial distress some of the doctors might possibly accept the flat fee proposition.

A \$4.50 fee cannot possibly buy proper medical and surgical attention to injured workmen, who are entitled to the best medical and surgical services that money can buy. We are at a loss to understand why an institution as large as the Lumbermens Mutual Casualty Company is alleged to be resorts to cutting the doctor's medical and surgical fees when the other insurance companies writing the same class of business continue to pay their bills on a fee basis, not on flat rates.

If the Lumbermens Mutual Casualty Company succeeds, it will probably force the companies handling similar business to adopt the \$4.50 fee plan or to discontinue writing compensation insurance, for no insurance company could compete with the Lumbermens Mutual Casualty Company in writing compensation insurance. The final answer would be for the industrial surgeon either to accept the \$4.50 flat fee or discontinue doing industrial work.

W. C. NORDHOLZ, M.D., Chicago.

Secretary-Treasurer, Chicago Society of
Industrial Medicine and Surgery.

INTRAVENOUS THERAPY AND VENOCLYSIS

To the Editor:—Reading the communication on the intravenous drip by W. Forrest Dutton in *THE JOURNAL*, October 20, was like hearing from an old friend, because his book *Intravenous Therapy* has been my vade mecum since its publication.

I was surprised to learn that any discussion had arisen over the priority of the intravenous drip. I had always ascribed that honor to Dr. Matas and never supposed that there was any question or doubt about it.

In my paper of December 1924 in *Southern Surgical Transactions* for 1924 will be found quotations with ample credit to Friedman, Penfield and Teplitz, Unger and Huess, Matas, Woodyatt, Sansum and Wilder. My "bid for fame" rests on the fact that I have devised an apparatus and worked out a technic by which this "means of grace" is made instantly available and its range of useful application expanded almost without limit in the field of therapeutics. By using the modus operandi that I employ, men all over the country have succeeded in achieving results considered impossible, as their letters to me will verify. For example, I have kept patients alive and in a fair state of physical prosperity for twenty-one days, excluding all other sources of nutrition. With the same technic, blood transfusions can be regulated with due regard to the ratio between delivery and distribution and dangerous reactions thereby avoided. By guaranteeing absolute rest to the stomach I have to date cured thirty-five cases of gastric and duodenal ulcers. Then why should I worry about priority? Thomas Edison neither discovered nor invented electricity, Henry Ford did not invent the automobile and Napoleon did not invent war.

I wish to say in defense of my so-called hybrid word that it was submitted before the Southern Surgical Association in December 1924 in the following language, which appears on the title page of my article as a footnote: "I feel very apologetic for the use of a word as the title of my paper that has not received the stamp of approval or been authorized by custom. But, in searching for a name that was descriptive and euphonious to apply to this somewhat rare therapeutic measure. I fell upon the term venoclysis by analogy. We have proctoclysis, hypodermoclysis; why not venoclysis?"

Seven years elapsed before any suggestions of its impropriety were registered. In the meantime it had become current and found its way into the newer dictionary (Dorland), which might be considered a mark of authoritative recognition. I believe that words, like people, should be rated according to their

utility rather than their origin. Some of our most useful and distinguished citizens sprang from a dual or dubious source.

If venoclysis is denied admission to our medical vocabulary, in order to be consistent we must banish such words as ovariectomy, appendectomy and almost all of those ending in the good old Greek suffix "itis." Even appendicitis, duodenitis and a host of others would have to go. Besides, venoclysis is such a nice word. It possesses euphony. It trips lightly off the tongue and falls musically on the membrana tympani. It at once proclaims its meaning and makes a proximate appeal to the average man and has rendered ten years of useful service.

G. A. HENDON, M.D., Louisville, Ky.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

NONSPECIFIC URETHRITIS

To the Editor:—A white man, aged 24, had a discharge from the urethra about ten days following illicit intercourse. There was some burning on urination as well as increased frequency. He was first seen by another physician, who took smears that were negative for gonococci. He was given two injections of mild silver protein by this physician, with a subsidence of the discharge. Because his doctor did not take his case seriously, he consulted me for further treatment. The discharge five days after it first appeared was seropurulent in character, which left a yellowish stain on gauze. I have given him injections of a silver antiseptic for the past three weeks with but slight improvement in the amount of the discharge. Diathermy to the prostate and prostatic massage have also been given without improvement. The patient is a lawyer and is considerably upset by his predicament, as he contemplates marriage within a few months. In about ten smears that have been taken and examined, gonococci have not been discovered, merely numerous pus cells. My first impression was gonorrhea, but since the condition did not yield to treatment and no specific organisms have ever been found, I felt that he might be suffering from a nonspecific urethritis. At the present writing, about six weeks after the onset, there is no frequency, urgency, nocturia or dysuria. The discharge still persists in spite of treatment and is almost serous in character with white specks and matting at the meatus. The teeth, tonsils and gallbladder are normal, and the Wassermann reaction is negative. He has been complaining of dull pains in the right lower quadrant of the abdomen for some time and was told by his doctor that he had chronic appendicitis. Could a prostatitis from a focal infection elsewhere give such a clinical picture? Is it possible that this man has a gonorrheal infection without my being able to find the organisms on smear? Please omit name.

M.D., New York.

ANSWER.—From the data submitted there is little evidence that a gonococcal infection is being dealt with in this case. The length of the incubation period, while not ruling it out, certainly minimizes this possibility. This presumption is strengthened by the fact that no positive smears have been obtained. To be unable to demonstrate gonococci in the profuse untreated discharge of a specific urethritis would be unusual.

The symptomatology presented and the clinical course outlined arouse the suspicion of an acute urethral flareup based on a preexistent pathologic condition of the lower urinary tract. The influence of trauma (sexual or otherwise), prolonged drinking, infections of the upper respiratory tract and distant foci has repeatedly been demonstrated in the activation of these otherwise dormant pathologic conditions. Great care must be exercised in this particular case to exclude the presence of seminal vesiculitis, which may be determined by the microscopic examination of the prostatovesicle fluid obtained on massage and stripping. If repeated massage reveals only normal bodies, attention is directed to the possible presence of a urethral stricture. Cysto-urethroscopic study is indicated should these studies fail to bring to light pathologic changes.

Treatment in this particular case will naturally depend on the results of these diagnostic measures. The presence of a seminal vesiculitis or prostatitis will require regular weekly massage followed by the through and through irrigation or deep instillation of some such solution as 5 per cent silvol. Should a strictured urethra be encountered, progressive dilation and instillation of the urethra is indicated. In those cases of nonspecific urethritis not complicated by prostatic or seminal vesiculitis or the presence of urethral stricture, irrigations of mercuric oxycyanide solution in 1:4,000 dilution act in most cases as a specific. This could well be used in the treatment of this case either with or without massage.

RECURRENT DISLOCATION OF SHOULDER

To the Editor:—A white man, aged 35, in good health, has a left shoulder which dislocates easily, with anterior dislocation, either being necessary to effect reduction. Please advise where suitable exercises for strengthening this joint may be obtained. Is surgery to close rent in capsule indicated? Kindly omit name.

M.D., Iowa.

ANSWER.—The treatment of recurrent dislocation of the shoulder depends to some extent on the nature of the condition. In some instances, defects in the head of the humerus that may be due to obstetric paralysis, infantile paralysis or congenital defects or to changes that occurred after the first dislocation may be present. Occasionally, as the result of fractures at the time of the first dislocation, the glenoid cavity is left deformed or with the anterior and inferior edge displaced. Fractures of the greater or lesser tuberosity of the humerus sometimes complicate the picture at the time of the first dislocation and the resulting diminution of function of the supraspinatus and infraspinatus muscles predisposes to repeated dislocations. Weakness of the supraspinatus and infraspinatus muscles as a result of injury or paralysis also predisposes to shoulder luxation.

The most common pathologic condition, however, is found in the capsule itself and consists of a wide rent in the anterior and inferior portion of the joint capsule and in detachment of this portion of the capsule from the margin of the glenoid cavity, occurring at the time of the first dislocation. Such defects tend to repair by scar tissue, which is usually overstretched each time that the head of the humerus slips out of the glenoid until the joint becomes so relaxed that it is no longer stable.

Judging from the brief description, the patient probably falls within the latter group. If there is no definite evidence of muscular weakness, particularly of the deltoid, supraspinatus and infraspinatus muscles, and no contracture of the pectoralis major, teres minor or latissimus dorsi, exercises cannot be expected to strengthen the joint. Operations for prevention of redislocation have been varied. Exposure of the joint in its anterior inferior aspect by way of the axilla and plication of the capsule has been advocated. Other surgeons have preferred to use strips of fascia lata for reinforcement of the relaxed joint. In some instances these fascial strips have stretched so that the defect in the capsule has recurred. Within recent years many orthopedic surgeons have adopted a technic described by Nicola, which utilizes the long head of the biceps muscle to stabilize the shoulder joint successfully. In the hands of those who have used it extensively, this procedure has been almost uniformly successful.

Other procedures that have not been widely adopted consist of the use of a tendon sling through the humeral head formed from one of the peroneal tendons of the foot or a procedure to deepen the glenoid by means of a bone graft driven into its anterior and inferior edge.

This subject has been briefly reviewed in a recent paper by Nicola: Recurrent Dislocation of the Shoulder, *J. Bone & Joint Surg.* 16:663 (July) 1934.

POSSIBLE LATENT SYPHILIS

To the Editor:—In November 1933 a Wassermann report of a patient was four plus alcohol antigen and four plus cholesterinized antigen. Physical examination was otherwise negative and there was no history of primary or secondary syphilis. A marital history was essentially negative. The man has three children living and well; a twin died soon after birth. He was given ten injections of 0.9 Gm. of neosarsphenamine intravenously and 2 cc. of iodobismutol intramuscularly, these medications being given at the same visit. Directly after the first course of ten injections he was given a second course, this time receiving eleven injections of the same medication and on March 24, 1934, at the end of the tenth injection a blood Wassermann reaction was one plus in alcohol antigen and one plus in cholesterinized antigen. He was then given a third course of ten injections of 0.75 Gm. of neosarsphenamine and 2 cc. of iodobismutol and following this last course on July 10 a blood Wassermann reaction was one plus in alcohol antigen and four plus in the cholesterinized antigen. What I should like to know is whether I am fully justified in trying to obtain a negative Wassermann reaction on this patient by further injections of neosarsphenamine. He is in excellent health and shows no symptoms of syphilis other than the Wassermann reaction. Any further suggestions you have in regard to this case will be appreciated. Please omit name and address.

M.D., New York.

ANSWER.—The diagnosis of latent syphilis in this patient cannot be completely substantiated until after the spinal fluid has been examined. Lumbar puncture with a laboratory examination of the spinal fluid, including cell count, protein estimation, quantitatively titered Wassermann reaction with amounts of fluid ranging from 0.1 to 1 cc., and a colloidal gold, mastic or benzoin test, should be done immediately. If the spinal fluid is positive, treatment must not only be continued to deal with the asymptomatic neurosyphilis, which is likely to progress if the patient's treatment is stopped at this point, but in all

probability should be altered to include the use of tryparsamide, fever therapy or both. If the spinal fluid is negative, treatment may proceed on the assumption that the patient has latent syphilis.

The studies of the Cooperative Clinical Group (Venereal Disease Information 13:317, 351, 371, 389 and 407, 1932; 14:1, 1933) show that about 35 per cent of all patients with latent syphilis are Wassermann fast, that the optimal amount of treatment for latent syphilis consists of a little over a year of continuous treatment with alternating courses of an arsphenamine and compound of bismuth or mercury, and a second year of intermittent treatment with three long courses of a bismuth compound separated by rest periods of from two to three months. This amount of treatment should be given regardless of serologic progress.

In this particular patient it appears that thirty consecutive weekly combined treatments of 0.9 Gm. of neoarsphenamine and 2 cc. of iodobismutol have been given. This is overtreatment. If the spinal fluid test is negative, it would be wise to give the patient a rest of two or three months, to be followed with an eight injection course of neoarsphenamine given without bismuth, and in a dosage not exceeding 0.6 Gm. This course might be immediately followed by a twelve injection course of bismuth preferably with an insoluble salt such as the salicylate, a rest period of two or three months, another course of bismuth, another rest period, a third course of bismuth, and then treatment discontinued, the patient to be followed with periodic physical examinations at yearly intervals for the remainder of his life.

DIET IN RENAL DIABETES

To the Editor.—Is there a renal diabetes? And what would be the proper diet restriction? I have had a patient under observation four years whose blood sugar ranges from 120 to 150. Only once did it go to 180. The urine of this patient presents a marked glycosuria constantly. The quantitative analysis of a twenty-four specimen is always close to normal.

H. H. RITTENHOUSE, M.D., Bridgeville, Pa.

ANSWER.—Cases of renal diabetes, more properly termed renal glycosuria, actually occur although they are not common. This diagnosis can be made only when it has been shown that sugar appears in the urine at a time when the blood sugar is below the usual kidney threshold value of 180 mg. per hundred cubic centimeters. It must of course also be established that the sugar which appears in the urine is dextrose and not some other form of carbohydrate, which is being ingested. The simple yeast fermentation test is usually sufficient for the latter purpose. The only treatment advised for renal glycosuria is to avoid undernutrition through loss of sugar in the urine, by supplying additional carbohydrate in the diet.

In regard to this patient, it is difficult to understand how he could present a constant marked glycosuria and still not show much sugar in the twenty-four hour quantitative analysis. Two possibilities suggest themselves. If the single urine specimens that have been tested qualitatively have been taken shortly after meals, they might show a markedly positive test. However, these specimens when diluted in the total twenty-four hour specimen containing much normal urine might give a low total sugar content. If this is the case, the patient has alimentary glycosuria. At present it is advisable to regard such patients as potentially or mildly diabetic and treat them accordingly. The other possibility is that the patient is excreting some other form of sugar than dextrose and that the qualitative sugar test is not specific for dextrose, while the quantitative method used is specific.

EPILEPSY AND SYPHILIS

To the Editor.—A man, aged 35, developed epilepsy at the age of 28 years. His past history is negative for allergy, migraine and convulsions in childhood. There has been no epilepsy in other members of his family. The first epileptic seizure occurred in 1927, at which time a four plus Wassermann reaction of the blood was disclosed. Since then he has had grand mal seizures at the rate of one every four to six months. In 1930 the blood Wassermann reaction was strongly positive; the blood sugar was found decreased to 83.3 mg. He was given seventeen injections of neoarsphenamine. Three months ago, during another seizure, the blood Wassermann reaction was found to be four plus, but the spinal fluid Wassermann reaction and serologic tests were not reported. He has had no treatment since 1930. Physical examination at present is entirely negative. There are no stigmas of syphilitic infection. What treatment should be instituted if the spinal fluid Wassermann reaction is positive and serologic tests show a syphilitic colloidal gold curve? If the latter are negative? Please omit name.

M.D., New York.

ANSWER.—Epilepsy due to syphilis is relatively rare in the absence of outspoken neurologic manifestations of syphilis. When it occurs in patients who have syphilis it is usually associated with dementia paralytica (which seems unlikely in

this case because of the long duration of the convulsions), or with a more or less purely vascular neurosyphilis. Although the neurologic changes in this case are not stated, it is probable that the patient has idiopathic epilepsy, which has no relation to syphilis. The spinal fluid should of course be examined. If the spinal fluid Wassermann reaction is positive in any dilution, regardless of other abnormalities in the cell count, protein content or colloidal gold curve, it would be desirable to treat the patient with fever, preferably malaria, which in turn should be followed by two years of continuous antisyphilitic treatment with alternating courses of tryparsamide, an arsphenamine and a bismuth compound. If the spinal fluid is normal, it may be stated that the patient has so far been inadequately treated for latent syphilis, whether or not associated with epilepsy. His treatment should be continued until he has received five full courses each of neoarsphenamine and a bismuth compound.

An effort should be made to control the epileptic seizures with phenobarbital, the dosage of which should be adjusted to suit the individual needs of the patient.

BRONCHIAL ASTHMA IN A SAXOPHONE PLAYER

To the Editor.—My brother, aged 24, had measles and diphtheria at the age of 6, the latter infection leaving him with a bilateral chronic purulent otitis media. Three years ago he presented allergic manifestations by violent and prolonged sneezing fits when he got out of bed in the morning. Two years ago he began to wheeze only while he slept. Last winter (1933) he was seized with a severe attack of bronchial asthma and coughing. He was relieved by epinephrine and morphine. From that time on exertion or walking against the wind always made him short of breath. One could hear him wheeze and cough. Roentgenograms were taken of his chest and sinuses with negative results. He was tested for irritants and was found markedly sensitive to feathers, rabbit hair and wool. He was mildly sensitive to dog, cat, horse and a few articles of food. He had a course of injections of stock dust vaccines without any apparent relief. Of course, his room is bare of any rugs, blankets and feathers, cotton and kapok having been substituted. For the past few months he has felt perfectly well during the day but every morning at about 5 o'clock he is awakened by a choking sensation and a paroxysm of coughing. He is spontaneously relieved at about 9 a. m., usually after a bowel movement. From this foregoing brief description will you please answer these questions: Is it possible that these attacks are initiated by an accumulation of feces in the bowel? Would a vaccine of the predominating fecal organisms be of any advantage? Would a stock vaccine of upper respiratory organisms be of any benefit? Is there a positive demand for him to discontinue his profession (saxophone playing)? Can you suggest any other drugs? I am and have been using potassium iodide, ephedrine and calcium. Any other suggestions that you have will be greatly appreciated.

M.D., New York.

ANSWER.—From the history and observations given there would seem to be no doubt that this patient is definitely allergic and has a true bronchial asthma. The chronic bilateral otitis media is probably of no importance here. The fact that he is short of breath on exertion would suggest the probability that the bronchial asthma is already complicated by a fairly severe emphysema; if this is true the emphysema has occurred very early in the course of the asthma; the saxophone playing, which further balloons out already distended lungs, is probably one reason, at least, for the early appearance of the emphysema. For this complication the best advice is to (1) quit playing the saxophone or any other wind instrument, (2) avoid overexertion and (3) apply some such instrument as was described by Alexander and Kountz (Symptomatic Relief of Emphysema by an Abdominal Belt, *Am. J. M. Sc.* 197:687 [May] 1934), in which a belt, pad and bolt are used to increase the abdominal pressure so as to push up the diaphragm and so lessen the emphysema.

The best treatment of bronchial asthma is, of course, to find the cause of the attacks and to remove it. It might be wise to retest the patient by complete cutaneous and intracutaneous tests, to remove all offending substances (allergens) completely, and to take prolonged injections of those allergens which are important and which cannot wholly be avoided; e. g., rabbit hair, wool, feathers, house dust and horse dander. Such a course of treatment might well extend over one to three years, beginning with injections twice a week for three or four months, then once a week for a month or two, then once in two weeks to keep up what immunity is acquired by the injections. Short courses of treatment usually fail.

In addition, it would be wise to sew in the mattress and pillows with a light rubber sheeting; this sheeting should then be washed once a week. This procedure is beneficial in many cases, probably because it markedly decreases the amount of house dust and fungi. The home should be kept clean with an electric vacuum cleaner; no sweeping or dusting should be permitted.

It is important, of course, to keep the bowels open, but there are no authentic data that show a relationship between bowel infection and bronchial asthma; vaccines prepared from fecal

organisms have given disappointing results. When success has followed such a vaccine the results are probably due to a nonspecific protein action and, in common with all such nonspecific methods of therapy, the results are only temporary in the vast majority of cases. Vaccines from the sputum offer a better chance of success, but here also the results usually are only temporary. A useful prescription for many cases of bronchial asthma consists of apomorphine hydrochloride 0.13 Gm., potassium iodide 20 Gm., and sufficient syrup of sarsaparilla to make 120 cc. The dosage is a teaspoonful every four hours.

The potassium iodide loosens the sputum and the apomorphine is an excellent expectorant. For severe attacks, subcutaneous administration of epinephrine hydrochloride in doses of from 0.5 to 1 cc. of the 1:1,000 solution is still supreme. Morphine should not be given except in a few cases in which epinephrine and other drugs have failed; and, when used, morphine should be injected in small doses with a great deal of caution. Some fatalities have followed the combined use of morphine and epinephrine. Ephedrine by mouth is often very efficient. The main problem here, however, is to find the cause and thoroughly eliminate it if possible, and to desensitize to those important causes which cannot be completely eliminated.

MUSCLE TWITCHING AFTER DEATH AND RIGOR MORTIS

To the Editor:—I was called recently to see a patient who had apparently been overcome by heat. He was a man, aged 41, of robust build, a heavy drinker of intoxicants, who had been in good health up to the day on which I was called. While doing heavy manual labor in the hot sun, he fell unconscious and on my arrival one hour later was still unconscious, almost pulseless. Blood pressure was 50 systolic, 30 diastolic; temperature was 108 F., and breathing was labored. His condition gradually got worse and he died in about half an hour in spite of stimulants and an ice bath. The interesting feature about this case and concerning which I would appreciate your opinion is the following: For at least forty-five minutes after this man appeared to be dead by the usual criteria, as absence of breathing and heart tones and the mirror test, there were spontaneous movements of the limbs, as flexing and extending the fingers, bending the knees slightly, and quivering of the tendons of the wrists and arms. The body would lie still for as long as ten minutes, and then a knee would rise as much as 2 inches from the bed or the fingers would move. The case was discussed with several physicians. Some say that such movements are possible post mortem in those dying of thermic fever or delirium tremens. The others maintain that these movements indicated that some spark of life was still present, that the movements would not have been possible if death had actually taken place, and that attempts at resuscitation should be continued as long as these movements continued. I would greatly appreciate your opinion on this question. If it is printed in the columns of THE JOURNAL, kindly omit my name and address.

M.D., Wisconsin.

ANSWER.—Spontaneous, fibrillar contractions of the muscles occur occasionally soon after death, especially in muscular individuals who die suddenly or after a very brief illness. High temperatures favor these contractions. A well known phenomenon is the fibrillation of the appendix of the right auricle of the heart, which may be observed even several hours after death (*ultimum moriens Halleri*). At necropsy, when the skin is being removed from the chest, fibrillar twitchings of the bundles of the serratus and major pectoral muscles are frequently seen. Rigor mortis too has to be taken into consideration and rigor mortis is apt to set in early on hot days. Since rigor mortis does not affect all muscles simultaneously but one group of the muscles after the other, certain movements may result, such as the rising of an arm or limb or a closing of the mouth. From the symptoms described there are no indications that the patient was still alive when pronounced dead.

HIGH DIASTOLIC BLOOD PRESSURE

To the Editor:—I have been unable to find in any of the textbooks a precise and logical explanation for the cause and significance of a high diastolic blood pressure. What is the pathologic basis and why is it considered a symptom of severe heart damage? Please omit my name.

M.D., California.

ANSWER.—High diastolic pressure may be found in essential hypertension, in chronic nephritis, in chronic lead poisoning, in some instances of increased intracranial pressure, as when a tumor presses on the medulla, in coarctation of the aorta, and in the rare cases of tumor of the suprarenal gland and pituitary basophilism. The immediate cause of high diastolic pressure is believed to be an increased tone of the peripheral blood vessels, especially the arterioles. The exact cause of the persistent increase of arteriolar tone is not known. Usually, though not always, arteriosclerosis and arteriolosclerosis are associated. When there exists a tendency toward arterial change, the development of arteriosclerosis is aided by the

hypertension. The resultant organic narrowing of the peripheral vascular bed is contributory to the development of a high diastolic pressure. Hypertrophy of the heart follows, invariably accompanied by some disease of the coronary arteries, often of an advanced degree. Cardiac irregularities, especially extrasystoles, may make their appearance; in some, auricular fibrillation develops, although usually not until late in the disease. Finally, signs of congestive heart failure become manifest. Thus, it is apparent that a high diastolic blood pressure should not be considered "a symptom of severe heart damage"; rather, severe heart damage may follow as a consequence of the hypertension, or of the associated coronary arteriosclerosis, or both.

DERMATITIS IN GLASS WOOL INDUSTRY—SALT IN HEAT EXPOSURE

To the Editor:—I have been doing some industrial work for a firm that makes glass wool. Minute particles of glass collect on the workers' skin and, together with the intense heat, produce a dermatitis, which is very irritating and difficult to combat. These men are required to take a shower at the end of the shift, but the cases of dermatitis continue. From the sketchy details given could you suggest treatment? What is the best and most economical method of treating drinking water for use in hot weather? We are using salt tablets. Could you recommend or suggest a modern textbook on industrial medicine?

H. A. CAMPBELL, M.D., Newark, Ohio.

ANSWER.—The dermatitis described is essentially the result of mechanical action on skins made more susceptible to injury through profuse sweating. The problem is not one of treatment but of prevention of further exposure. Exhaust systems should be installed wherever practically adaptable to the entrainment of small glass particles. Protective garments worn by workers will serve as a barrier against contact with these glass slivers, but in hot weather it is not always feasible to wear gauntlets and neck cloths, because of obvious discomfort. The application of water soluble soap to the skin when dry will provide some protection but may not prove to be entirely adequate to the situation.

The use of salt tablets in drinking water supplied for the purpose of replacing the chloride losses in perspiration has proved satisfactory and economical. Certain objections may be raised to the ingestion of large tablets of salt as being less desirable from a hygienic point of view than the intake of saline solution or loose salt. However, under industrial conditions the use of tablets has proved more expedient.

Below are listed several publications on industrial medicine and hygiene:

- Dr. Alice Hamilton's "Industrial Toxicology," New York, Harper & Brothers, 1934 (contents mostly limited to occupational diseases).
- Dr. Alice Hamilton's "Industrial Poisons in the United States," New York, Macmillan Company, 1929 (similar, but larger volume).
- Kober and Hayhurst's "Industrial Health," Philadelphia, P. Blakiston's Son & Co., 1924 (standard textbook on occupational diseases with extensive information on industrial hygiene and industrial medicine).
- Dr. Carey P. McCord's "Industrial Hygiene for Engineers and Managers," New York, Harper & Brothers, 1931 (primarily devoted to industrial hygiene, with chapters on industrial medicine and occupational diseases).

USE OF DINITROPHENOL

To the Editor:—A white woman, aged 33, married, has been under my care since Feb. 19, 1934, for the treatment of obesity. Her height is 5 feet 5 inches (165 cm.) and her original weight was 236 pounds (107 Kg.). Dinitrophenol sodium (Eastman Kodak) was used; the original dose was 1½ grains (0.1 Gm.) three times a day, later increased to the same amount four times a day. The patient lost 31 pounds (14 Kg.) in the period from February 19 to July 15. During this period she showed no untoward effects. Perspiration was marked. Since July 15 the loss of weight has ceased and there has been a gradual gain of weight, amounting at present to 8 pounds (3.6 Kg.). This has been associated with cessation of perspiration and constipation. The drug is potent, since some of the same batch is effective on other patients. There has been no limitation of the diet. Your suggestions will be greatly appreciated. Should the dose be increased? Kindly omit name.

M.D., Connecticut.

ANSWER.—Some patients who have been given dinitrophenol for long periods may develop a partial tolerance to the drug. In this patient medication should be stopped for two weeks, and then treatment resumed with a dose of 0.1 Gm. three times a day. After two weeks of this dose, if weight loss is not secured, the dose may be increased again to 0.1 Gm. four times a day, or if it proves necessary, even to as high as a total of 0.65 Gm. daily. The symptomatic response is the best guide as to the upper limits of dosage. It should not be overlooked that weight control is fundamentally a problem of balancing food intake against its use as energy. If the patient uses the medication as an excuse for greatly increased food intake, no reduction drug can be successful. It would therefore be

better to establish this patient on an adequate but not excessive diet before resuming the dinitrophenol medication. In many cases this measure permits the use of much smaller doses of dinitrophenol.

CASTOR OIL AND QUININE FOR THE INDUCTION OF LABOR

To the Editor:—A patient, several days overdue, was given castor oil and quinine to induce labor, after taking which she did not feel any fetal movements. After twenty-four hours she started in labor and at this time no fetal heart tones could be heard. A normal baby was born which to all appearances had been dead from twenty-four to thirty-six hours. Are there any cases on record in which castor oil and quinine have caused the death of the fetus when given at full term? The mother had no idiosyncrasy to quinine sulphate, but no cause except the medication could be found for the death of the baby. What is the general opinion of the profession in using this method of inducing labor? Kindly omit name.

M.D., Michigan.

ANSWER:—There seems to be not a little evidence that castor oil and quinine sometimes cause the death of the fetus in utero, though it is not easy to prove the fact since occasionally, when the gravida goes over term, the fetus dies without apparent cause.

Gellhorn (*Am. J. Obst. & Gynec.* 13:779 [June] 1927) claims that quinine can be fatal to the fetus, and more recently E. L. King of New Orleans has said the same. It is not known how this comes about. Some uteri react to quinine but most do not, and there has been no proof that tempestuous uterine contractions regularly follow the quinine in the cases in which the child has died. A frequent finding has been meconium-discolored liquor amni.

In the case cited it seems as if quinine (or perhaps the oil) caused the death of the fetus.

The dose of quinine should be reduced to a single capsule of 0.2 Gm., or 3 grains.

USE OF SCHILLING DIFFERENTIAL HEMOGRAM

To the Editor:—Are there any large cities in the United States using (with confidence) the Schilling differential count other than St. Louis? It is being used as a routine in several large hospitals in St. Louis. What, in general, is the Association's opinion of the procedure? What literature references other than Gradwohl's translation of "The Blood Picture" by Schilling can you give me? I shall greatly appreciate any information you may be able to furnish me.

R. C. PETERS, M.D., Kirkwood, Mo.

ANSWER:—Schilling began the writing of his simplified index in 1911. By 1925 his method was in common use in Germany and many European clinics. During the past few years the method has come into use in this country. Many large cities other than St. Louis use the Schilling hemogram. It must not be assumed, however, that this method or any other laboratory procedure is a short cut in the formulation of a clinical diagnosis. It is a valuable source of information when intelligently used, and by adding another feature to the mosaic which in its entirety represents a diagnosis or a prognosis, it is of distinct value. Excellent discussions on the theory and application of the Schilling hemogram may be found in

Pepper, O. H. P., and Farley, D. L.: *Practical Hematological Diagnosis*, Philadelphia and London, W. B. Saunders Company, 1933.

OPERATIVE PROCEDURE IN COLITIS

To the Editor:—A man, aged 35, has suffered for four years from mucous colitis, during which time he has been treated with diathermy, autogenous vaccines and whatnot, but with no success. Finally in 1932 he was advised to consent to an operation. A colostomy was performed in August 1932. Since then he has put on weight and looks and is perfectly healthy, his only complaint being a constant mucous discharge from the rectum. The family history and personal history are essentially negative. What can you tell me regarding the prognosis in a case of this sort, and is there any hope for a resection? If there is, how long after operation is such possible? Kindly omit name.

M.D., New York.

ANSWER:—Colostomy is rather unusual treatment for "mucous colitis." Colostomy occasionally has been performed for chronic ulcerative colitis, when the disease is limited to the distal segments of the large intestine and associated with unusual stricture or fistula. Whether or not resection could be done would depend on the activity and complications of the disease. If the lining of the bowel seems to be in fairly good condition and the lumen is reasonably roomy, the colonic stoma might be closed. If resection becomes necessary, it is well to wait until the active disease in the lower segments of the intestine has subsided.

PILONIDAL CYST OR FISTULA IN ANO

To the Editor:—A traveling salesman, aged 35, otherwise in perfect health, has anal fistula of ten years' standing. He has no pain except when hairs grow into an opening, and only a small discharge occasionally. But at different times there has been a discharge from five or six different openings. I hesitate to attempt the classic operation owing to the extent of mutilation probably necessary with loss of time and danger of failure of some kind. I wonder whether it is worth while to try autogenous vaccine or nonspecific protein with or without a purse-string or temporary mucous flap for the rectal opening. Also, what is the danger in delay? Does recovery ever occur spontaneously? Current literature on this subject seems to be scarce. I would like as much information as you can give in this column. Please omit name.

M.D., Wisconsin.

ANSWER:—The description of the condition suggests pilonidal cyst with multiple openings. If this is the case, there is no communication with the anal canal and the treatment consists in a wide excision of all tracts and the cyst itself. If, however, the condition is a complicated fistula in ano with multiple openings, radical surgery is the only method that offers any possible chance of cure. This consists in a careful dissection of all the tracts and going through the sphincter at the point where the tract enters the anal canal. All the tracts must be left open to granulate in by themselves; otherwise there would be a recurrence of the condition.

SURGICAL REPAIR OF OLD PERINEAL LACERATION

To the Editor:—What is the preoperative and postoperative care for an old complete laceration of the perineum in a woman, aged 38, who has had the condition for eighteen years? Continence of feces is maintained by a band of scar tissue. In the repair should this band of scar tissue be sacrificed and the torn sphincter ends brought together, or would you retain the band of scar tissue and rebuild the perineal body above it? What percentage of such old cases are successfully repaired by bringing the torn sphincter ends together? Kindly do not mention name.

M.D., New York.

ANSWER:—Preoperative care is unnecessary except for a simple enema, which should be given not later than four hours preceding operation.

The supporting band that maintains continence may perhaps be spared. The preliminary incision is preferably made high and sufficiently curved laterad to the anus to permit the dissection downward of a short wide flap over the anus. Extensive denudation and repair of the perineum constitute a prominent feature in the procedure. Bringing together the torn sphincter ends is helpful but is a lesser factor and does not usually suffice unless there is a coincidental perineal repair. An illustrated description of the technic will be found in Curtis's *Text-book of Gynecology*, ed. 2, page 272.

THYRONINE OR DESICCATED THYROID

To the Editor:—In case there was a deficiency of the thyroid such as after thyroidectomy, which would be the best to give, and why, thyroxine or desiccated thyroid? I do not mean to consider the cost. Please omit name.

M.D., Utah.

ANSWER:—Desiccated thyroid would be superior because it contains all the thyroid secretion and has been found to possess greater calorogenic activity than an amount of thyroxine of equal iodine content when administered by mouth. This is attributed both to the existence in desiccated thyroid of a thyroxine-peptide complex (Harington and Salter, *Biochem. J.* 24:456, 1930) which is more soluble than thyroxine and possibly less readily destroyed in the digestive tract and also to the activation or transformation of diiodotyrosine, which is an important normal constituent of the thyroid gland. It is to be supposed that as replacement therapy the desiccated thyroid containing both these substances would more nearly serve as a complete substitution product.

ENDEMIC GOITER

To the Editor:—Is Forest Park, Pa., in a goiter belt? Is the condition aggravated when patients with hyperthyroidism move into a goiter district? The patient whom I have in mind has hyperthyroidism and wishes to go on her vacation to Forest Park, Pa., and has sought my advice on that point. Please omit name.

M.D., New York.

ANSWER:—Forest Park, Pa., is not in what could be called a goiter belt, although endemic goiter does occur there. The incidence of toxic goiter does not run parallel to that of endemic goiter. In some regions where there is more endemic goiter there is less toxic goiter, but this is not everywhere true. There is no reason to think in this case that the hyperthyroidism would be aggravated by a change in locality such as that mentioned. More would depend on the amount and nature of the rest obtained during the vacation.

OXYURIS VERMICULARIS

To the Editor.—Please send me information with regard to the treatment of adult infestation with *Oxyuris vermicularis* by means of aluminum subacetate. My patient is a man, aged 35, who has been infested for a period of ten years. According to my information, aluminum subacetate is the best treatment over a period of time. If it is your opinion that other medication would be more effective, will you please outline such treatment? Please omit name and address.

M.D., New York.

ANSWER.—It is not probable that solution of aluminum subacetate is any more efficient than would be any other astringent, such as tannic acid solution, because the adult females, the only ones that can be reached by this treatment, are dislodged without difficulty from the anus and rectum by almost any form of enema. The young parasites, on the other hand, which inhabit the small intestine, are not reached by any other treatment than by anthelmintics, such as santonin, oil of chenopodium, or tetrachloro-ethylene taken by mouth. Santonin is given in doses of 0.01 Gm. for each year of age not to exceed an adult dose of 0.2 Gm. It is best to give one dose daily for a week. Tetrachloro-ethylene is at present preferred to oil of chenopodium. It is given in 0.5 cc. capsules, in an adult dose of 2 to 3 cc., followed in two hours by a saline purge such as sodium sulphate. As it may cause transient dizziness, the patient is best confined in bed for the day. Colon irrigations should be combined with the internal treatment, and quinine sulphate 1:1,000 solution is probably as good as any other agent.

PREPARATION OF CADAVERS

To the Editor.—In *Queries and Minor Notes* in *THE JOURNAL*, Oct. 7, 1933, page 1173, the preparation of cadavers for dissection in tropical countries is described. Is it necessary to use this solution of phenol, glycerin and alcohol in this country? If this solution is used for injection, can the immersion of the cadaver in a solution of 3 per cent phenol and water be eliminated? I do not plan to prepare a cadaver for dissection until the latter part of October, when it should be a little cooler here. Would this make a difference in the preparation? To save you looking this town up on a map, I want to tell you that it is located in southern Texas about 60 miles west of Brownsville.

LLOYD M. SOUTHWICK, M.D., Edinburg, Texas.

ANSWER.—It is absolutely necessary to use this solution or some similar one anywhere in this country. This one contains no arsenic; the use of arsenic for this purpose is prohibited in several states. If the cadaver is to be completely dissected within three months, immersion is not absolutely necessary; covering, when not being dissected, with wet cloths, and a big oilcloth sheet may be substituted.

VENOUS ECTASIA OR MELANOMA

To the Editor.—A man, aged 60, suddenly developed two bluish colored areas on the inner margin of the lower lip, about 0.125 mm. in diameter. These spots are perfectly flat, are not tender, and can be made to change color slightly on pressure. They are slightly larger than a year ago when they first appeared, but two more similar spots have appeared under the upper lip.

M.D., Massachusetts.

ANSWER.—The differential diagnosis lies between venous ectases and metastatic melanoma. The statement that the spots change color on pressure favors the diagnosis of vascular lesions, and the probabilities also weigh on that side; but the problem is so important that it is deemed best to have the case carefully studied by a specialist before treatment is instituted.

If, as seems probable, the decision is in favor of the venous dilatations, radium can be used with good results: a half strength plaque screened with 0.1 mm. of lead and applied for three periods of an hour each on three days within the same week. This may be repeated after an interval of a month or six weeks.

IMPETIGO

To the Editor.—During the last few months I have seen several cases of a skin lesion that resembles impetigo. Most of the patients are girls of the upper grade or high school ages. The lesions are scattered with no particular arrangement, but the hands and face are particularly affected. They resemble impetigo, but the crusts are not so heavy and the discharge is rather less purulent than in impetigo. Sometimes they itch considerably. The individual lesions are very persistent but finally clear up, leaving pigmented areas that are very disfiguring. They are very resistant to treatment. It seems to me that they clear up in spite of, and not because of, any medication, though I have tried all the usual agents. Have you any suggestions as to what it is and what to do for it?

E. R. HUCKLEBERRY, M.D., Garibaldi, Ore.

ANSWER.—There is little doubt that the condition described is impetigo contagiosa. The discharge in impetigo is more often thin and straw colored than purulent, and the crusts are not necessarily heavy. The itching is typical. The resistance to treatment, however, is unusual. The crusts should be

removed with warm water and soap; a saturated solution of boric acid is applied and then a 5 per cent ointment of ammoniated mercury. Short exposures to ultraviolet rays will hasten the cure. Five per cent silver nitrate solution is recommended in resistant cases.

NORMAL AND ABNORMAL TEMPERATURE

To the Editor.—I would appreciate very much your giving me the following information: What is normal temperature? What is the highest temperature to be considered normal in adult males? In adult females? In children? Is there such a thing as a physiologic temperature running higher in certain individuals which is normal for them? If so, how is it determined and how much elevation has been recorded in such individuals?

J. D. RILEY, M.D., State Sanatorium, Ark.

ANSWER.—The normal temperature of man and of woman averages 37 C. (98.6 F.) and 37.1 C. (98.78 F.) except for the first week of life. Axillary temperatures have been correlated with age, as follows:

In the first ten days.....	37.75 C. (99.95 F.)
Ten days to puberty.....	37.43 C. (99.39 F.)
Fifteenth to twentieth year.....	37.19 C. (98.94 F.)
Twenty-first to seventieth year.....	36.85 C. (98.33 F.)
Eightieth year.....	37.26 C. (99.06 F.)

The extreme variation in this table is 1.43 degrees F. The table also answers the question of the temperature of children. The variations being normal for the various age groups, individuals apparently enjoying good health have been known to have temperatures higher than those given. However, no deviation greater than 1.8 degrees F. is to be considered normal (Hewlett). A rectal temperature above 37.2 C. (98.96 F.) is considered by some as evidence of disease.

CHILD WITH CONGENITAL SYPHILIS

To the Editor.—Should a child with congenital syphilis untreated be excluded from attending public school?

EDWARD JOYCE, M.D., Hurley, S. D.

ANSWER.—In general, no. Children with prenatal syphilis by the time they reach school age no longer present infectious lesions even though untreated. Their attendance at school should be encouraged in every way possible, for they are frequently somewhat above the ordinary in intelligence, and disabilities and handicaps in the form of intercurrent complications such as interstitial keratitis should be compensated for in every possible way so far as the child's education is concerned. It is particularly inhuman and quite unnecessary from the public health standpoint to add to the burdens of these children either stigmatization or the loss of intellectual opportunity by exclusion from school.

CLEFT PALATE

To the Editor.—In cases of inoperable cleft palate, at what age and how successfully can dentures be used to close the cleft? How often do they have to be changed and is the average "good dentist" able to handle such an assignment? The patient I have in mind was taken to one of America's leading medical men in this line a few months after birth. He did not believe operation advisable at that time and told the parents to bring the child back at the age of 18 months. They brought the baby back and he told them to wait two years more. The cleft does not appear to be closing up at all. The two year period has about elapsed.

PAUL R. HOWARD, M.D., Monmouth, Ill.

ANSWER.—It is hardly practical to fit a plate in an open palate before the six year molars erupt. The question arises as to whether this is an inoperable case. Most of these patients can be operated on to advantage between the age of 1 and 2 years; there are a few that have a much better chance of success if operation is postponed until the first molar teeth are fully erupted, or even until the six year molars have erupted.

Any man doing general dentistry who would take sufficient interest in the case would be capable of handling it if the age and conditions are suitable for a plate.

SEBACEOUS CYSTS

To the Editor.—I would appreciate information concerning the destruction of sebaceous cysts on the lobule and areolar portions behind the ear. Are there any satisfactory sclerosing agents that may be injected? Would fulguration or desiccation currents be of any value?

D. C. MALCOLM, M.D., Onaga, Kan.

ANSWER.—At times roentgen treatment will cause small sebaceous cysts to disappear. From four to eight treatments are required at weekly intervals. The dose is approximately 75 roentgens. Either filtered or unfiltered radiation may be used. This amount of treatment is safe. Unfortunately, the effect on the cyst is uncertain. Radium may be used instead of x-rays.

Surgical diathermy may be used. One way to use this method is to make a small opening into the cyst with the cutting current and a needle electrode. Then the inner surface of the cyst wall is electrodesiccated. Surgical diathermy may be followed by considerable reaction, sloughing and, perhaps, an objectionable scar. At times the result is excellent.

The injection into the cyst of sclerosing substances after the contents of the cyst have been evacuated, substances such as phenol (carbolic acid) or a concentrated solution of trichloroacetic acid, may effect the desired result, but not infrequently a discharging sinus remains.

Many believe that the best method is scalpel excision with healing by first intention.

NEURITIS OF VULVA

To the Editor—I have under my care a woman, aged 58, who complains of vulval pain. The pain seems to be localized in the soft parts. Physical examination is absolutely negative as far as I can ascertain. Would you be kind enough to outline the possibilities and the treatment advised? Please omit name.

M. D., District of Columbia

ANSWER.—Pain in the soft tissues of the vulva, independent of a demonstrable lesion, is not uncommon. Neuritis is the most frequent cause. Alcohol injection relieves some cases. Nerve resection is occasionally advisable.

In making certain that there is no local pathologic condition, it is essential to rule out sensitive areas at the orifices of the Bartholin gland ducts, as well as tender caruncles, minute lesions caused by repeated traumatism at intercourse, and discomfort incident to a small rectocele. Many patients are entirely relieved of vulval sensitiveness after learning that entrance into the vaginal canal should be made with care not to traumatize the anterior wall; pressure posteriorly seldom causes discomfort.

PROPHYLAXIS OF SEED WARTS

To the Editor.—The superintendent of schools informs me that the physical director is finding many seed warts among the high school pupils, especially among the girls. They have scrubbed the gymnasium floor each day and had the pupils immerse their feet in a solution of corrosive mercuric chloride. Can you give me any information regarding prophylactic treatment for this condition?

M. D., Iowa.

ANSWER.—Since the etiology of "seed warts" is obscure, the prophylaxis is somewhat indefinite. Various investigators have been able to produce warty lesions by inoculation, and it is believed that the infected organism is a filtrable virus and that injury is necessary for the portal of entry. For prophylaxis, Hazen suggests mopping the surface with a saturated solution of salicylic acid in alcohol. If this cannot be borne, the use of alcohol alone also seems to be beneficial.

EPHEDRINE FOR DILATING PUPILS

To the Editor.—Please give me information on what strength ephedrine solution to use for dilating pupils in presbyopia.

ROBERT MONFORT, M. D., Cheboygan, Mich.

ANSWER.—From 5 to 10 per cent of the salts of ephedrine.

BILATERAL EPIDIDYMITIS

To the Editor.—In Queries and Minor Notes in THE JOURNAL, October 6, I noticed a communication on bilateral epididymitis and signed M. D., Colorado. In the treatment outlined I saw no mention made of the use of diathermy. In my experience I have found no other therapy that gives such satisfactory results in epididymitis. I use the Wappler epididymitis clamp, applied laterally to both testicles, with plenty of soap suds to make a good connection. I give one half to three quarters of an hour treatments daily and follow each treatment with an intravenous injection of 5 cc. of a 10 per cent solution of calcium chloride (ampules). I continue this treatment for a month if necessary. The testicles will return to normal size, leaving practically no nodulation in the epididymis. I use a current strength of from 750 to 1,200 milliamperes, beginning with the former and gradually working up. I mention the Wappler clamp because it permits of adjustment to any sized swellings and is perfectly insulated so that the patient very quickly learns to carry out the treatment himself. CHESTER H. WOOLSEY, M. D., San Francisco.

HYDROCHLORIC ACID IN HAY FEVER

To the Editor.—In the answer to the query on hydrochloric acid in hay fever, on page 938 in THE JOURNAL, September 22, you mention the prescription in the *Journal of Allergy* in September 1930. In the *American Journal of the Medical Sciences* for October 1927 a similar prescription is given and, as I remember it, this was not news at that time. I have used the prescription at times with good results.

J. K. WILLIAMS WOOD, M. D., Willow Grove, Pa.

* Examined in medicine and surgery.
† Verification of graduation in process.

District of Columbia Reciprocity Report

Dr. W. C. Fowler, secretary, Commission on Licensure, reports 12 applicants licensed by reciprocity from Jan. 29 to July 15, 1934. The following schools were represented:

School	LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
George Washington University School of Medicine.....(1931)			Maryland
Georgetown University School of Medicine.....(1931)			Maryland, Virginia
Howard University College of Medicine.....(1930)			Maryland, Virginia, (1931) Georgia, Virginia
Hahnemann Medical College and Hospital, Chicago.....(1911)			Iowa
Northwestern University Medical School.....(1924)			Iowa
Columbia College, College of Physicians and Surgeons.....(1895)			New York
Cornell University Medical College.....(1905)			New Jersey
Osteopath			California

South Dakota January Report

Dr. Park B. Jenkins, director, Division of Medical Licensure, reports the written and practical examination held in Pierre, Jan. 16-17, 1934. The examination covered 13 subjects and included 110 questions. An average of 75 per cent was required to pass. Four candidates were examined, all of whom passed. Three physicians were licensed by reciprocity and 1 physician was licensed by endorsement. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
State University of Iowa College of Medicine.....(1932)			86
University of Michigan Medical School.....(1931)			84
University of Minnesota Medical School.....(1927) 86, (1933)			84
School	LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
Rush Medical College.....(1932)			Iowa
College of Physicians and Surgeons, Medical Department Kansas City University, Kansas.....(1897)			Kansas
St. Louis University School of Medicine.....(1914)			Oklahoma
School	LICENSED BY ENDORSEMENT	Year Endorsement Grad.	of
Rush Medical College.....(1932) N. B. M. Ex.			

South Dakota July Report

Dr. Park B. Jenkins, director, Division of Medical Licensure, reports the written and practical examination held in Rapid City, July 17-18, 1934. The examination covered 14 subjects and included 95 questions. An average of 75 per cent was required to pass. Six candidates were examined, all of whom passed. Four physicians were licensed by reciprocity. The following schools were represented:

School	PASSED	Year Grad.	Per Cent
Northwestern University Medical School.....(1931)			88
University of Minnesota Medical School.....(1927)			86
Creighton University School of Medicine.....(1928) 87, (1933)			86, 87
University of Nebraska College of Medicine.....(1933)			88
School	LICENSED BY RECIPROCITY	Year Grad.	Reciprocity with
Bennett College of Eclectic Med. and Surg., Chicago.....(1915)			W. Virginia
State University of Iowa College of Medicine.....(1928)			Iowa
John A. Creighton Medical College.....(1906)			Nebraska
University of Nebraska College of Medicine.....(1921)			N. Dakota

Book Notices

A Manual of the Practice of Medicine Prepared Especially for Students. By A. A. Stevens, A.M., M.D., Consulting Physician to St. Agnes Hospital, Philadelphia. Thirteenth edition. Cloth. Price, \$3.50. Pp. 685, with 16 illustrations. Philadelphia & London: W. B. Saunders Company, 1934.

The fact that this is the thirteenth edition attests the usefulness of this manual. The author has held to his original purpose to give to the book an elementary character and he has not added much to its size, although in this edition a number of new subjects appear for the first time. Some of these are massive collapse of the lung, psittacosis, hyperinsulinism, osteitis fibrosa cystica and agranulocytic angina. It must have been difficult for the author to keep the book so condensed, in view of the many important developments in medicine that have come about since the book was first published in 1892. The material under some subheadings is confined to a few lines, and that gives certain portions of the volume a character suggestive of a medical dictionary. The author has met the same difficulty that many other medical book writers have in that it is almost impossible to include the latest advances in view of the rapidity with which they are made. In the discussion of heat stroke and heat exhaustion, for example, nothing appears to have been said about the use of common salt as a prophylactic, which advance came out of the experience gained in the care of workers who are building the so-called Hoover Dam. The author mentions, however, that in the treatment of heat stroke the intravenous and subcutaneous injection of salt solution has proved beneficial in some cases.

Selected Surgical Papers (1876-1914). By Frederic S. Dennis, M.D., F.R.C.S. In two volumes. Boards. Pp. 940, with illustrations. New York: Privately Printed, 1934.

These selected papers were edited and printed by the author with few changes, and those only mistakes in the original articles. He has two reasons for publishing these as a collection of papers: first, to cover his personal experience during the periods of septic surgery, of the open treatment of wounds, of the antiseptic method of Lord Lister and finally following the advent of asepsis; second, to present in tangible form the history, during the life of a single individual, of the greatest science and art that have been employed in aid of humanity. One reads of the marked improvements in surgery during the period of septic surgery by following sound surgical principles even before antiseptics was known. The treatment of a large series of cases with compound fractures reported in 1884 would be a credit to a modern hospital surgical service. Covering the range of surgery as it was known during the years to the present generation are presented most excellent results for that time, in resections for tuberculosis of the knee, gunshot wounds of the abdomen, open operation on fracture of the patella, ligation for deeply located aneurysms, suprapubic cystotomy, trephining for skull fracture, carcinoma of the breast, gangrene of the lower extremity, brain tumor, and various operations on the gastrointestinal tract. His conclusions reported in 1899 about the operative indications for complications of appendicitis will bear

studying at this time. The breadth of knowledge in surgery as evidenced by his writings is stupendous. The surgical principles that he emphasized are as true today as when written, although the technic has changed. The author has performed a real service in printing in book form this collection of papers. They should be read by the student as well as the surgeon for a broader grasp of surgical principles and for the personal historical facts of the most important surgical era known.

Lærebog i intern medicin. Udgivet af Knud Faber, Peter F. Holst og Karl Petré. Binder I-IV. Third edition. Paper. Pp. 623, with 194 illustrations; 592, with 136 illustrations; 727 with 149 illustrations; 799, with 106 illustrations. Copenhagen: Gyldendalske Boghandel—Nordisk Forlag, 1927-1934.

This edition of the textbook for internal medicine is written in collaboration by a number of Scandinavian physicians who mostly have used their respective vernaculars in penning their part of the work, so that some chapters are in Danish, others in Swedish and others in Norwegian. The work gives a comprehensive description of each disease in particular and is divided into four volumes.

The first volume treats of infectious diseases and discusses infection in general, immunity and the use of serum therapy, passive immunization and active immunization and their combined employment, serum diagnosis and chemotherapy. Each infectious disease is described extensively, and chronic infections, animal parasites and poisonings by inorganic and organic agents are given in detail.

The second volume gives a thorough description of the diseases of the respiratory system, subdivided into diseases of the buccal cavity, the throat and the nose, diseases of the bronchi and the lungs, tuberculosis and diseases of the pleura; then diseases of the circulatory system, the mediastinum and the spleen, and the hemorrhagic diatheses. Tuberculosis is described under the headings of tuberculosis of the lungs and miliary tuberculosis, and in the chapter on the diseases of the circulatory system reproductions of electrocardiograms and schematic curves help to clarify the text.

The third volume describes the diseases of the digestive tract, subdivided into diseases of the esophagus, the stomach and the intestine; the diseases of the peritoneum, of the pancreas, of the liver, the gallbladder and the portal vein; the hematogenous medical diseases of the kidneys and the localization renal diseases; the diseases of the renal pelvis and of the urinary bladder; the diseases of the endocrine glands, and the avitaminoses. The diseases of the endocrine glands are thoroughly discussed and the chapter on avitaminosis is unavoidably short, while the diseases of the digestive system and of the kidneys are given the place of honor and are described competently and minutely.

The fourth volume treats of the diseases of the nervous system, the diseases due to disturbances of metabolism and the diseases of joints and muscles. It is quite natural that the diseases of the nervous system occupy the largest part of the volume; they are competently and completely described and are subdivided into organic nervous disorders, extrapyramidal diseases, diseases of the peripheral nerves, trophovasomotor neuroses, epilepsy, migraine and constitutional psychopathies. The diseases due to disturbances of metabolism are ably presented and the treatment of the diseases of the joints and muscles includes chapters on hydrotherapy and light therapy. The volume closes with a chapter on roentgen therapy in internal medicine. This textbook presents an imposing aspect on account of its size, it covers completely the whole field of internal medicine, it has been written by able physicians, it is beautifully edited, and it offers a profusion of excellent illustrations. It is unfortunate that the language difficulty prevents its general use among students and physicians.

Volumetric Analysis. By H. P. Starek, M.A., Head of the Science Department, the Technical College, Kingston-on-Thames. Cloth. Price, \$3. Pp. 259, with 11 illustrations. Baltimore: William Wood & Company, 1934.

The author gives a detailed presentation of the methods and problems of volumetric analysis and lists a variety of determinations. The subject is introduced by a brief description of volumetric apparatus and of the properties of the chief acid reagents used. Next a chapter is concerned briefly with the

source and properties of the most common indicators. Since the book is evidently primarily written for the beginning student, the theory of indicators is confined to a seven page chapter. The volume is then further divided into sections on acidimetry and alkalimetry, oxidation and reduction, precipitation methods, and some applications of these methods.

Sets of problems follow each of the main sections of the book. Ample illustrations are given of the various types of reactions. Almost all equations, however, are presented from a molecular point of view; no attempt is made to give ionic reactions. Special determinations intended for pharmaceutical students are indicated with Latin titles in parenthesis; some of the more difficult determinations with potassium permanganate, iodine and some others are set aside for "degree" and "advanced" students. The uses of potassium iodate and titanous chloride, as well as of each of the common oxidizing agents, are detailed in separate chapters. Finally, a brief chapter is devoted to explanation of volumetric processes in the estimation of two or more substances in a mixture or solution. Laboratory directions, especially for the beginner, are for the most part written into the text in the same type as explanatory material and aid in combining theory with practice, a procedure often neglected by students. Much care is taken to indicate clearly the stoichiometric relations involved between the reagent solution and the end product sought. In this manner the text also serves as a good reference work for the beginning student.

Papers of Charles V. Chapin, M.D.: A Review of Public Health Realities. Selected by Frederic P. Gorham, A.M., Sc.D. Edited by Clarence L. Scamman, M.D. With a foreword by Haven Emerson, M.D. Cloth. Price, \$1.50. Pp. 244. New York: Commonwealth Fund; London: Oxford University Press, 1934.

The collected papers of Dr. Charles V. Chapin will be recommended to every one who is interested in public health. Dr. Chapin, for many years health officer of Providence, R. I., has contributed some of the most important thoughts to modern public health. It was he who made the first comprehensive survey of public health activities of state government under the direction of the Council on Health and Public Instruction of the American Medical Association in 1915. On this preliminary work has been built much of the modern movement for appraisal of public health work. It was Dr. Chapin who early pointed out wasteful public health activities as opposed to effective lines of public health work. It was Dr. Chapin who pointed the finger of scorn at the "fetish of disinfection" and distinguished between justifiable measures and unjustifiable measures for the spread of infectious diseases. It was under his direction that the city of Providence not only maintained but utilized with telling effect the longest continuous record of vital statistics available from any American city. The collection published under this title is a representative selection. The book is illustrated with a picture of Dr. Chapin. It should have a place in the library of every public health worker. Physicians will find it intensely interesting and stimulating, especially in view of the growing interest of the profession in preventive medicine. The book contains among other features a complete bibliography of Dr. Chapin's most important contributions along the line of public health.

Modern Treatment in General Practice. Edited by Cecil P. G. Wakeley, D.Sc., F.R.C.S., F.R.S.E. Cloth. Price, \$4. Pp. 426, with illustrations. Baltimore: William Wood & Company, 1934.

These articles were written by specialists for the general practitioner. They were first published in the *Medical Press and Circular*, some as individual articles and others as symposiums. The authors of these articles generally are well known members of the profession in England. There was no attempt apparently to cover the entire field of medicine, and the subjects discussed, aside from those in the symposium, do not have any direct relation to one another. Some of the subjects discussed are acute circulatory failure, diabetic coma, blood transfusion, migraine, insomnia, chronic hoarseness, anemias and pyorrhea. One of the articles on the spa facilities in England opens with the statement that "if the value of spa treatment in the cure or prevention of disease were sufficiently well known, many sudden deaths and many years of suffering and crippleddom might be prevented, and many useful lives prolonged in happy content, and our spas would be overcrowded."

If such is the case, it would seem to be the duty of those who are expert and widely experienced in spa treatment to present evidence that will convince the profession quite generally of the accuracy of the foregoing statement.

Epidemic Myalgia: Bornholm Disease. By Ejnar Sylvest, M.D. With a foreword by Dr. Th. Madsen, Director of the Danish State Serum Institut, Copenhagen. Translated from Danish by Hans Andersen, M.D. Paper. Price, 8 Danish crowns; 7/6. Pp. 155. Copenhagen: Levin & Munksgaard; London: Humphrey Milford, Oxford University Press, 1934.

The original Danish edition of this monograph was discussed in the editorial columns of THE JOURNAL, February 10, under the title of epidemic myalgia, or pleurodynia. The editorial summary gives references to the reports of the outbreaks of the disease in the United States. Probably the disease is more frequent than is now realized. The translation into English of Sylvest's excellent monograph will be of great help in spreading the knowledge of epidemic myalgia, also called in Danish literature Bornholm disease on account of the great many cases occurring in the Danish island Bornholm, where Sylvest, a practicing physician, made his valuable observations. Bornholm is not the place, however, where the disease was recognized first.

Acute Intestinal Obstruction. By Monroe A. McIver, M.D., Surgeon-in-Chief, Mary Imogene Bassett Hospital, Cooperstown, N. Y. Cloth. Price, \$7.50. Pp. 430, with 62 illustrations. New York: Paul B. Hoeber, Inc., 1934.

This book thoroughly covers all phases of acute intestinal obstruction. The author has concentrated particularly on its clinical aspects. Approximately a sixth of the book is given over to a discussion and evaluation of experimental methods used in the study of intestinal obstruction. References made to important contributions in other studies of the disease and an adequate bibliography are presented at the end of each chapter. The book is well illustrated by reproductions from the original articles, to which frequent reference is made. Most of the illustrated cases used by the author were taken from the records of the Massachusetts General Hospital. The book is readable, and the author's knowledge of the disease, as evidenced by numerous contributions to the literature on intestinal obstruction before the publication of the book, makes it of exceptional value.

Medicolegal

Malpractice: Limitation of Actions; Concealment of Right of Action.—In June 1929 the defendant-dentist extracted ten of the plaintiff's teeth and prepared a denture. About three months later the defendant, attributing the pain of which the plaintiff complained to the fit of the denture, filed a small portion of it, administered a drug to alleviate the pain, and replaced the denture. On three other occasions, at intervals of about three months, the plaintiff returned to the defendant with the same complaint and the defendant each time followed the procedure just noted. Finally, at the suggestion of the defendant, the plaintiff, in August 1930, consulted another dentist, who discovered that three broken roots were embedded in the plaintiff's jaw bone and removed them. The pain disappeared. In May 1931 the plaintiff sued the defendant-dentist for malpractice and obtained judgment. The dentist then appealed to the court of appeals of Louisiana, Orleans.

The defendant contended that the Louisiana statute which requires tort actions to be instituted within one year from the accrual of the cause of action barred the plaintiff's suit. The statute referred to by the defendant [Civil Code, art. 3537], said the court, normally runs from the day on which the damage was sustained. An exception is recognized, however, in cases in which the plaintiff, through some act of the defendant, is kept in ignorance of the fact that damage has been done. The evidence here shows that for about fourteen months immediately following the extractions the defendant attempted to alleviate the pain from which the plaintiff was suffering. During this time the plaintiff did not know that roots were still embedded in his jaw bone and that they were the cause of the pain. Under such circumstances the statute did not commence to run until the plaintiff discovered the cause of his injury. So long

as the plaintiff continued to rely on the professional advice of the defendant and so long as the defendant continued to assure the plaintiff that the pain was being caused by the denture, there was no obligation on the part of the plaintiff to seek redress in the courts. It would be inequitable to permit a physician or dentist, who discovers that he has negligently injured his patient and continues to treat the patient, concealing the true condition until the action is barred, to plead then that the action is brought too late. It is immaterial whether the physician or dentist discovers the mistake and intentionally conceals it or negligently fails to discover it. The important factor is that through reliance on the physician's or dentist's care the patient has not discovered that the injury which he has sustained resulted from the fault of the physician or dentist.

The court of appeals could find no error and the judgment in favor of the plaintiff was accordingly affirmed.—*Perrin v. Rodriguez (La.)*, 153 So. 555.

Compensation of Physicians: Liability of Patient for Consultant's Fee; Creation of an Account Stated.—On the advice of his family physician, the defendant engaged Dr. H. G. Tobey to treat his son, who was suffering from mastoiditis. Dr. Tobey decided that an operation was necessary and suggested to the family physician that Dr. G. L. Tobey Jr. be engaged to operate. At the request of the family physician, Dr. G. L. Tobey Jr. did operate. On the failure of the defendant to pay for the services rendered, Drs. H. G. and G. L. Tobey Jr. brought suit for their fees. The defendant claimed that he neither engaged Dr. G. L. Tobey Jr. to render any medical or surgical services nor consented to his operating. He asserted that he engaged Dr. H. G. Tobey.

It is inconceivable, said the supreme court, Columbia county, New York, that the defendant did not know what physician was to operate on his son or that he had no knowledge as to who was treating and caring for his son during convalescence. Ordinary paternal interest, observed the court, would have compelled a father to ascertain these facts. Even had the services been performed without the consent or knowledge of the father, he would still be liable. In so holding, the court quoted as follows from *In Matter of Sherman's Estate*, 6 Pa. Co. Ct. Rep. 225, in which a patient was attended by a physician who subsequently, and without the patient's consent or knowledge, called another physician in consultation:

If the right in the consulting physician to compensation for this service is without legal merit, then the law is a reproach to conscience. That it [this question] has not been passed upon hitherto, means nothing; or rather, it means that it has never been questioned, any more than the right of the physician to charge his patient with the drugs he has purchased, or the nurse he has hired for him, when drugs and nursing were indispensable to his recovery.

As to the value of the plaintiffs' services, the court thought there had been an account stated. The defendant had admitted, in letters to "Dr. Tobey," that he had received a bill from a collection agency and that the sum stated therein was justly due and owing. He had made a payment on account with a promise to pay the bill in full. Where an account is rendered, said the court, the person receiving it is bound to examine it, and, if he admits it to be correct, it becomes an account stated and binding on both parties. It is conclusive unless fraud and mistake or other equitable considerations are shown which make its enforcement improper.

The court accordingly entered a judgment in favor of the plaintiff physicians.—*Tobey v. Nelson (N. Y.)*, 270 N. Y. S. 201.

Society Proceedings

COMING MEETINGS

American Academy of Orthopedic Surgeons, New York, Jan. 14-16. Dr. Philip Lewin, 104 South Michigan Boulevard, Chicago, Secretary.
Puerto Rico, Medical Association of, Santurce, Dec. 14-16. Dr. Julio R. Rolenson, Box 3403, Santurce, Secretary.
Radiological Society of North America, Memphis, Tenn., December 3-7. Dr. Donald S. Childs, 607 Medical Arts Building, Syracuse, N. Y., Secretary.
Southern Surgical Association, Sea Island, Ga., Dec. 11-13. Dr. Robert L. Payne, 142 York Street, Norfolk, Va., Secretary.
Western Surgical Association, St. Louis, December 7-8. Dr. Albert H. Montgomery, 122 South Michigan Boulevard, Chicago, Secretary.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

American J. Obstetrics and Gynecology, St. Louis

28: 473-628 (Oct.) 1934

- Endometrial Findings in Functional Menstrual Disorders. B. M. Anspach and J. Hoffman, Philadelphia.—p. 473.
Further Studies on Pelvic Architecture. W. E. Caldwell, H. C. Moley and D. A. D'Esopo, New York.—p. 482.
*New Measurement (Clinical) for Estimating Depth of True Pelvis: Preliminary Communication. W. Schuman, Baltimore.—p. 497.
*Survey of One Thousand Gonococcus Complement Fixation Tests Performed with Serum of Female Patients in an Outpatient Clinic. W. M. Brunet and B. S. Levine, Chicago.—p. 501.
Treatment of Trichomonas Vaginalis Vaginitis with Sodium Perborate and Quinine. I. W. Kahn, New York.—p. 511.
Treatment of Diseases of Cervix by Electrosurgical Unit, with Especial Reference to Cervicitis. M. L. Stadium, New Orleans.—p. 514.
Cancer and Prolapse of Uterus. F. V. Emmert and J. B. Taussig, St. Louis.—p. 521.
Kidney Function in Pregnancy: III. Water Diuresis in Toxemias of Pregnancy. Mary A. McManus, Gertrude A. Riley and J. C. Janney, Boston.—p. 524.
*Sedimentation Rate and Schilling Index in Pregnancy. R. J. Griffin, Philadelphia.—p. 532.
Macrocytic Hyperchromic Anemia in Pregnancy: Report of Case and Review of Literature. W. E. Studdiford, New York.—p. 539.
Relation of Anemia of Pregnancy to Hydremia and Its Treatment with Aqueous Equine Liver Extract and Glycerated Iron. O. Richter, A. E. Meyer and J. P. Bennett, Chicago.—p. 543.
Study of Seventy-Nine Patients Delivered by Litzko Extraperitoneal Cesarean Section. H. T. Burns, New York.—p. 552.
Analysis of One Hundred and Fifty-Seven Cases of Cesarean Section. G. A. Palmer, Akron, Ohio.—p. 557.
Pregnancy Complicated by Fibroids. J. R. Eisaman, Pittsburgh.—p. 561.
Accidental Injection of Iodized Oil into Uterine Veins. S. R. Meaker, Boston.—p. 568.
Embedding of Ovary in Tubal Pregnancy: Review. H. C. Falk, New York.—p. 572.
Effect of Shape of Pregnant Uterus on Mechanism of Labor. J. M. Laferty, Philadelphia.—p. 582.
Another Method of Anesthesia in Obstetrics. C. W. Schumacher, St. Louis.—p. 587.
Bleeding Time and Coagulation Time in the New-Born. M. Weiner and C. E. Bailey, Denver.—p. 593.
Granulosa Cell Tumor of Ovary in Child with Precocity. P. B. Bland and L. Goldstein, Philadelphia.—p. 596.
Krukenberg Tumor of Ovaries. A. Saccone and Sarah Gordon, New York.—p. 601.
Enormous Ovarian Cyst. W. F. Gemmill, York, Pa.—p. 603.
Practical Obstetric Manikin. J. B. Jacobs, Washington, D. C.—p. 605.
Combined Inlet and Outlet Pelvimeter. S. Hanson, Stockton, Calif.—p. 608.
Postpartum Paralysis: Report of Unusual Case. A. Cline, Dayton, Ohio.—p. 611.
Bicornate Uterus with Pregnancy in Each Horn. A. B. Barrett, Nashville, Tenn.—p. 612.
Simultaneous Gangrenous Twisted Ovarian Cyst and Acute Gangrenous Appendicitis. L. P. Kasman, Brooklyn.—p. 614.

Measurement of Depth of True Pelvis.—Schuman calls attention to the use of a new external measurement, based on the suggestions of Caldwell and Moley, and intended to estimate the depth of the true pelvis. The perpendicular distance from the tuberosity of the ischium to the iliopectineal line is measured easily by using the ordinary pelvimeter. It should be taken immediately after the intertuberous diameter has been measured, and, with one end of the pelvimeter still on the tuberosity, the other end is swung round until at a point on the upper border of the superior ramus of the pubis directly perpendicular to the tuberosity. The author has found that this distance averages 11.5 cm. Allowance must be made for pubic and gluteal fat; in the patient of normal build, 1 cm. should be allowed for soft parts, and in obese patients, 2 cm. He calls this diameter the "right or left pubotuberous."

Gonococcus Complement Fixation Tests.—Brunet and Levine performed routine gonococcus complement fixation tests

with the blood serum of 1,000 female patients in order to establish with the aid of clinical study the practical value of this laboratory procedure. They conclude that in routine clinical work gonococcus complement fixation results should be considered specific only after certain factors have been taken into consideration. In the early stages of a suspected new infection, the persistence of a positive reaction, regardless of its intensity, is of importance and points to the specificity of the reaction. The fact that a large proportion of the cases known to have gonococcal activity give negative results is due entirely to the use of a strongly lytic complement unit, which renders negative otherwise weakly positive results. The method by which gonococcus antigen is at present prepared generally makes the use of a high complement unit imperative. Positive complement fixation results are obtained rarely in the instance of old cured patients, for the gonococcus antibody persists only from one to six weeks following the disappearance of the organisms. Therefore in the absence of a seropositive syphilis, a persistently positive gonococcus complement fixation test establishes active gonorrhea. If a new infection is excluded definitely, the existence of a chronic activity is diagnosed. Complicated cases of gonococcal infection in the female do not react any more strongly than do simple infections, except so far as they are, as a rule, of longer standing. The time factor influences the reaction. In cases of salpingitis, especially of the chronic type, complement fixation offers possibly a means for the differentiation of gonococcal from nongonococcal salpingitis. To lessen the frequency of the occurrence of nonspecific results, and possibly to eliminate them, a complement dose of high lytic potency should be used, as was suggested by Kolmer. With such a procedure of gonococcus complement fixation many of the early and weak reactions are rendered negative, but the procedure as a whole is placed on a safe level of reactivity.

Sedimentation Rate in Pregnancy.—Griffin states that the sedimentation rate of the erythrocytes increases progressively with each month of normal pregnancy. The rate in the ninth month is approximately five times that given for the average normal nonpregnant woman. There is a return practically to normal by the fourth week after delivery. A group of patients with toxic symptoms showed more rapid sedimentation rates than the average for normal pregnant women in the same month of gestation. The average readings were from 10 to 15 points higher by the percentage method of recording. There is a mild regenerative type of activity of the bone marrow during pregnancy, as shown by the Schilling index.

Susceptibility of Red Cells to Malaria.—Eaton proposes the following hypothesis: The red cell is susceptible to infection with malaria only when it is in the reticulocyte stage. Schizonts that do not infect promptly are phagocytized. Anything that increases the actual number of reticulocytes favors the progress of the disease. The rate of production of schizonts follows a fairly regular curve, which can be worked out easily. The rate of production of red cells follows a curve that is not worked out so easily. If a crest in the schizont curve meets a crest in the red cell curve, the conditions for extension of the disease are present. If on the other hand a crest in the schizont curve meets a trough in the red cell curve, the conditions for regression or even spontaneous cure of the disease are present. The conditions are subject to such enormous variation that they probably would defy mathematical analysis.

Cardiac Infarction and Tolerance of Dogs to Digitalis.—Bellet and his associates determined the tolerance of dogs to digitalis at various intervals after ligation of the coronary artery: half an hour after ligation of the coronary artery, four days later (during the stage of acute and subacute infarction) and from six weeks to six months later (during the stage of chronic infarction). The tolerance of these animals was compared with that of animals in a normal control series. Dogs standardized within half an hour after ligation showed no diminution in tolerance to digitalis as compared with those in a control group. During the stage from acute to subacute infarction there was a diminished tolerance to digitalis, which averaged from about 20 to 30 per cent below the average of the figures for the normal controls. In the animals with chronic infarction, in which the area of infarction was considerably smaller than in the acute or subacute stage (standardized from

six weeks to six months after ligation of the coronary artery), the tolerance was less than that of the normal animals but higher than that of the group with the subacute infarctions. The diminution in tolerance after ligation of the coronary artery depends apparently on the presence of infarction and probably also on the extent and stage of the infarcted area. The observations lend support to the clinical impression that digitalis in massive doses may be dangerous during the stage of subacute and chronic infarction and that it should be used with caution in such cases.

Empyema and Anaerobic Streptococci.—Fisher and Abernethy report seven cases of severe purulent infections, four of which presented putrid empyema, two pulmonary abscess and one multiple hepatic abscesses. In the four cases the empyema developed suddenly and was not a complication of a preceding chronic pulmonary infection. The studies indicated that the pleural infection was associated with intrapulmonary infection. This relationship was proved at necropsy in two of the cases. Anaerobic streptococci were present in each case, although the associated organism, which constituted the flora, was not consistently of one type. That the method of laboratory cultivation is of special importance is demonstrated by the fact that streptococci were recovered chiefly under anaerobic conditions, when the usual aerobic methods failed. Of the four strains of streptococci, two were viridans, one non-hemolytic and one hemolytic. In biologic and cultural characteristics they resemble in some ways the *Streptococcus putridus* of Schottmüller and the *Streptococcus intermedius* of Prévot. The latter organism was found in pulmonary conditions, but both these types are described as strict anaerobes, whereas those in the authors' cases were facultative anaerobes. Their studies indicate that the anaerobic streptococcus was the chief etiologic agent in the four cases of putrid empyema, in one of which it invaded the blood stream, produced multiple metastatic abscesses and endocarditis and was obviously the cause of death. Surgical drainage seems to offer the best chance of cure. Intravenous injections of nearsphenamine are probably of value in cases in which spirochetes are found, especially if they are in the sputum also. Extensive cellulitis of the thoracic wall, with the formation of gas, may follow surgical drainage or aspiration, owing to the leakage of the organisms along the path of the needle or the incision. A therapeutic procedure that may offer additional help in dealing with such effusions is the replacement of the empyema by air. Anaerobic streptococci were found to be the predominant organisms in the two cases of pulmonary abscess in which cultures were made directly from the pus at operation. In the case of pyophlebitis with multiple hepatic abscesses due to an anaerobic streptococcus an attempt was made to identify the streptococci with the various types reported in the literature. They do not fulfil completely the characteristics of any one group. Cultures of one strain were capable of producing empyema in rabbits when injected intrapleurally. Other strains gave varying results under similar conditions. Evidence is presented to indicate that these streptococci may often be pathogenic for man and for animals.

Lymphedema of Extremities.—Allen believes that the confusion regarding lymphedema is due to its relative rarity, to an inadequate knowledge of its etiology, bacteriology and pathology, and to the absence of a comprehensive classification. He feels that the pertinent data from the records of 300 cases observed at the Mayo Clinic offer an opportunity to fill many of the gaps. He reviews the important facts regarding lymph vessels and lymph, presents a classification of lymphedema, gives descriptions of the various types of lymphedema, discusses the mechanism of production, and considers the differential diagnosis of lymphatic edema and other types of edema. He points out some of the gaps in the knowledge of lymphedema in order to stress the need for further investigation and in order to explain why it is impossible to present a completed picture of the disease. He feels that the shortcomings noted should encourage rather than discourage the investigator of lymphedema; the problems that remain unanswered are so important that any progress will be worthy of note.

Carcinomatous Endarteritis of Pulmonary Vessels Resulting in Failure of Right Ventricle.—Greenspan presents four cases of carcinomatous lymphangitis. Three were secondary to scirrhous adenocarcinoma of the stomach and one

to adenocarcinoma of the sigmoid. In all four, the physical signs of the pulmonary involvement were inconspicuous and yet the clinical picture was characterized by an initial cough and by rapidly increasing dyspnea and deepening cyanosis. Two of the patients died with evidences of rapidly progressive failure of the right side of the heart. The roentgen diagnosis of carcinomatous lymphangitis of the lungs was confirmed by necropsy in two cases. In the three cases of scirrhous adenocarcinoma of the stomach, necropsy revealed a widespread obliterative endarteritis of the smaller pulmonary vessels. In two of these cases the vascular changes were sufficiently extensive to explain the failure of the right side of the heart. This obliterative endarteritis is due mainly to the influence of the plugging of the neighboring perivascular lymphatic channels by carcinoma, so-called carcinomatous lymphangitis. The vascular occlusions result to a minor degree from carcinoma cell emboli that have entered the pulmonary circulation by way of the thoracic duct and the superior vena cava. A few carcinoma cell emboli were found that had accumulated blood platelet thrombi in their passage through the blood stream and subsequently had undergone rapid organization after they had come to lodge in small branches of the pulmonary arteries. In cases of right ventricular cardiac failure presenting no significant pulmonary or cardiac involvement, the possibility of a diffuse secondary carcinomatous lymphangitis of the lungs with accompanying obliterative endarteritis of the pulmonary vessels should be considered.

Heat in Schizophrenic Reaction.—Cameron bases the following observations on approximately 10,000 temperature readings in fifty schizophrenic and fifty control subjects: 1. The internal temperature in the schizophrenic group was throughout the day slightly lower than that in the nonschizophrenic psychotic group, both groups being at room temperature. 2. There is evidence to show that at room temperature the mechanism of heat control in the schizophrenic group is more active than in the nonschizophrenic group. 3. Observations on exposure to extreme cold suggest that the mechanism of heat control acts more sharply and more strongly in the schizophrenic than in the nonschizophrenic group. 4. Exposure to extreme heat reveals no weakness in the mechanism of heat control in the schizophrenic group. 5. The response to the ingestion of food is more marked but less well sustained in the schizophrenic than in the nonschizophrenic group. 6. These observations are not consistently true for the individual subject, but only for the group. It is doubtful whether it would be wise to accept the suggestion afforded by any one of the experiments alone, but the fact that all tend to reveal the same condition, together with the large number of observations, makes the author feel justified in according a fair degree of probability to the contentions that (1) heat production in the schizophrenic is lower than in the nonschizophrenic group and (2) heat control in the schizophrenic group is more active than in the nonschizophrenic group, this being apparently in the nature of a compensation for the decreased output of heat.

Facial and Meningeal Angiomatosis Associated with Calcifications of Brain Cortex.—Krabbe reports six cases that present a characteristic clinical picture, nearly all showing a combination of epileptic fits and angiomas of the face. To these, the most prominent symptoms, may be added, as frequent symptoms, mental debility and a slight spastic hemi-

plegia on the side opposite to the angioma of the face. Furthermore, the patients are sometimes rather fat. If roentgen examination is made, a characteristic shadow appears inside the skull: a distinct sinuous shadow, presenting exactly the shape of the surface of the brain, showing both gyri and sulci, often with double contours. Generally, this shadow is localized in the occipital lobe. Histologic examination of the brain shows that the shadow is due to calcification of the outer layers of the cortex, not of the pia mater. This presents in some parts an abundant vascularization but not a true angioma. The calcification consists of numerous small, mostly microscopic, granules of lime salts, localized in the second and third layers of the cortex. In these layers the nerve tissue is in great part destroyed and replaced by fibrillar neuroglia. In the case described the occipital lobe, in which the processes were localized, had shrunk and was sclerotic. Otherwise the brain seemed fairly normal; only in places were the same modifications seen to a slight degree. The changes in the brain probably are not secondary to angiomas of the pia mater. The syndrome must be related to a more generalized malformation of the organism (as in tubercous sclerosis), consisting in the formation of angiomas of the face, slight angiomatous modifications of the pia mater, aplasia of the occipital lobe of the brain with (probably secondary) sclerosis and calcification of the aplastic part. The malformations probably originate in fetal life. The calcifications are related not to a tumor but to a congenital defect and malformation. Hence, operation is not indicated. Roentgen treatment may perhaps be administered to please the patient. No striking results are to be expected from treatment, however, since regeneration of aplastic brain tissue is not possible. Symptomatic treatment for the epileptic fits and mental hygienic treatment for the mental defects must be considered as the only therapy.

Cutaneous Localization in Pedicle Flap.—Douglas and Lanier cite a case in which a pedicle flap from the right nasolabial region was substituted for the right four fifths of the lower lip. The dissection of the flap resulted in denervation of the outer fourth (roughly) of its free end, but the original nerve supply entering from the pedicle was left intact and sensations from this sensitive portion were referred mainly to the upper lip and cheek. Results of localization tests carried out on the sensitive part of the flap revealed a progressive shift of "local sign" from the upper lip and cheek to the lower lip. The development of reorientation required several months. A transitional stage was observed, involving considerable confusion and a tendency to localize sensations in an area intermediate between the old and the new locations of the flap. This tendency was interpreted as a resolution of the conflict arising between the old and the new orientation habits. No reference was observed on return of sensitivity to the denervated portion of the pedicled flap. The ability to localize sensations within this area began to return within six weeks and was apparently coincident with the ingress of nerve fibers from the edges of the chin and lip to which the flap was attached. The results indicate that "local sign" depends mainly on habit formation, involving the association of cutaneous impulses with the kinesthetic impulses.

Treatment of Verrucae by Bismuth Sodium Tartrate.

—Shellow employed an aqueous 15 per cent solution of bismuth sodium tartrate in the treatment of ninety-seven lesions of various types of verruca occurring in seventy-three patients. The skin about the lesion is prepared by washing with soap and water; then iodine and alcohol are applied. A fine hypodermic needle is used to pierce the skin just outside the zone of hyperkeratosis and directed downward and inward toward the base of the verruca at the most active point, the end of the needle remaining just above the corium. From a half to 2 minims (0.03 to 0.14 cc) of the bismuth sodium tartrate solution is injected, according to the size of the lesion. In from one to three days after the injection a dark hemorrhagic area appears, visible through the keratotic surface. This denotes that the drug has taken effect. In the markedly keratotic hard type of ordinary verruca vulgaris this phenomenon may not always be seen. In most cases, from one to three days after the first injection there has been either cessation of growth or a marked diminution of pain. The latter is the case so often accompanies the painful verruca. In the papillomatous type two to seven days. All papillomatous types decidedly after the first injection, and in the papillomatous types the surface becomes smoother. If within fifteen to twenty days following the appearance of the hemorrhagic top of the verruca has not come off or if it has not fallen out, the keratotic tissue may determine whether any activity is still present. In some instances, after a lapse of from fourteen to twenty days following the initial injection the removal of this keratotic center reveals an underlying normal appearing dermis. If after two weeks of further observation verrucous tissue is seen, the lesion may be reinjected. In ninety-seven lesions, most of them having been treated previously by other measures, eighty-nine were cured, five and three showed no improvement. Sixty-seven lesions of the painful palmar or plantar variety, and eighteen of the verruca vulgaris type occurring on the dorsum of the feet.

a
be
hav
tifying

experimental or laboratory evidence in its favor that is not highly controversial, and no consistent demonstration of any characteristic microscopic pathology. A statistical study of a series of 150 cases of acute rheumatic fever and 250 cases of chronic atrophic polyarthritis has revealed no significantly higher incidence of familial tuberculosis or associated visceral tuberculosis than that found in a group of 250 control cases. Of a series of seventy-five cases in which a diagnosis of chronic atrophic polyarthritis had been made and in which the pathologic characteristics of a single joint were determined by microscopic examination of tissue or inoculation of guinea-pigs, eight patients were found to be definitely tuberculous. In each of these the tuberculous identity of the joint was suspected prior to the examination of the tissue or inoculation of guinea-pigs, but the association with multiple arthritis was confusing.

Treatment of Chronic Osteomyelitis.—Bozsán believes that an area of aseptic bone necrosis anywhere in the skeletal system may be treated advantageously by connecting the necrotic segment with an adjacent living segment of bone by means of drill channels. He feels that the formulation of this working principle is fairly justified by the satisfactory results obtained after its application in cases of Legg-Calvé-Perthes disease, osteochondritis dissecans, Osgood-Schlatter disease, intracapsular fractures of the neck of the femur, and slipping and slipped upper femoral epiphyses; in all these conditions aseptic bone necrosis is the main pathologic feature. The spontaneous healing process of aseptic bone necrosis, brought about by any cause, is the substitution of living bone in the place of necrotic bone, effected by the slow penetration of tissue elements and capillaries of the adjacent living bone. The drilling of channels into the necrotic area presents nothing but the breaking of broad avenues to facilitate this invasion by new vessels. While attempting to compare the characteristic features of aseptic bone necrosis and necrosis in the wake of septic processes, such as suppurative osteomyelitis, the author has come to the conclusion that, in spite of the seemingly great discrepancies, in the last analysis no difference exists. The clinical and experimental observations of Bancroft on hematogenic osteomyelitis demonstrated that the substitution process is just as active in the recovery of these septic necroses as in the aseptic necroses. This circumstance, rather than the supposed attenuation of the infection, is the reason, in the author's opinion, for the good results obtained from the simple drill hole evacuation of chronic bone abscesses recommended by Brickner. Since the natural healing process in both aseptic and septic necrosis appeared to be analogous, it seemed possible that septic necrosis might respond favorably to the treatment that was found effective in aseptic necrosis. Therefore the author induced substitution and revitalization of necrotic areas of bone in chronic osteomyelitis by connecting these areas with living bone segments by means of saw cuts and drill channels. The procedure in the first two cases—observed one and three-fourths years and one year after operation, respectively—proved successful.

Operation for Delayed Union in Fractures.—Carter describes an operation for delayed union or nonunion in fractures which is based on the principle of drill holes proposed by Beck of Kiel. The procedure consists of boring a number of small holes through the fragment ends, across the line of fracture. This gives rise to a certain amount of hemorrhage, allows the penetration of new blood vessels and furnishes fresh bone pulp, thus creating a stimulus to new bone formation. The author has employed the method in five cases: one of fracture of the shaft of the femur, two of fracture of the tibia and two of fracture of the forearm. It is his opinion that, in those fracture cases with delayed union or nonunion for which no cause can be found which would indicate definitely some other form of treatment, the simplicity and harmlessness of this procedure warrant giving it a trial before resorting to open operation. When the drilling is properly done, the risk of infection is negligible and prolonged hospital confinement is unnecessary. If the treatment is successful, roentgenographic evidence of callus formation will be seen in from three to five weeks; if not, open operation can be performed then. The

only contraindication to the performance of the drilling is an open, infected fracture.

Treatment for Fracture of Olecranon.—Rombold presents a technic for suture of a fracture of the olecranon. The skin incision extends from 2 inches distal to the olecranon to 5 inches proximally, and it is curved either laterally or medially to avoid the olecranon. The skin and subcutaneous tissue are reflected widely, exposing the ulna, the fracture, the olecranon and the triceps tendon. The old clot is cleaned from the fracture. The shaft of the ulna is drilled one-half inch distal to the fracture and well in front of the posterior cortex. Two strips of triceps tendon one-fourth inch wide and 3 inches long are used for the suture of the fracture. The proximal ends, the edges and the muscle-apposed surfaces are freed, and their insertions at the lateral and medial surfaces of the olecranon are left intact. The lateral strip is passed through the drill hole from the lateral to the medial surface and the medial strip is passed from the medial to the lateral surface. They are then tied to each other and sutured through the knot after the fractured fragments have been fixed snugly in position. The wound is closed in layers. The arm is carried in a sling for a week to ten days. Use up to the point of pain is encouraged after four or five days. Four patients have been operated on with perfect functional results.

*Some Unusual Cases of Filariasis of Scrotum and Groin. H. H. Young, Baltimore.—p. 383.

Filariasis of Scrotum and Groin.—Young reports five cases, four of which are quite similar and one an ordinary case of chronic epididymitis, which occurred following cystoscopy. This patient came from the same locality in Colombia, South America, but presented entirely different lesions. In the first three cases and the fifth the disease started as a peritesticular or periepididymal disease. It was characterized by the ultimate formation of a dense mass of tissue, which in two cases has enveloped completely and compressed the epididymis without involving the tissues of the epididymis. The disease has traveled upward outside the spermatic cord more or less loosely attached to the external fascia of the cord, in some instances forming large globular masses and in others very fine lines, suggesting lymphatic canals with small, bead-like enlargements along the course of the canal. The inguinal glands were enlarged. Ordinary bacterial inflammation, tuberculosis, syphilis or malignant disease has not been observed. The pathologic process is characterized particularly by the deposit or growth of large numbers of round cells, which have ultimately gone on to the formation of a marked fibrous sheath or covering. The tunica vaginalis in some instances has been involved extensively with adhesions to the testicle, but the testicle itself has been free from disease, although compressed and distorted by the fibrous tissue in one case. The intra-scrotal cord produced by the disease has been characterized also by the presence of much vascularity, and round the walls of the blood vessels are numerous areas of round cell infiltration. There are spaces that may be lymph nodes, but they contain no material in the stained sections, and nothing suggesting either a large or a small worm or larvae, or detritus resulting from the presence of a dead worm, has been found. Nevertheless, it seems evident to the author that the disease is filarial in origin.

Treatment of Verrucae by Bismuth Sodium Tartrate.—Shellow employed an aqueous 15 per cent solution of bismuth sodium tartrate in the treatment of ninety-seven lesions of various types of verruca occurring in seventy-three patients. The skin about the lesion is prepared by washing with soap and water; then iodine and alcohol are applied. A fine hypodermic needle is used to pierce the skin just outside the zone of hyperkeratosis and directed downward and inward toward the base of the verruca at the most active point, the end of the needle remaining just above the corium. From a half to 2 minims (0.03 to 0.14 cc.) of the bismuth sodium tartrate solution is injected, according to the size of the lesion. In from one to three days after the injection a dark hemorrhagic area appears, visible through the keratotic surface. This denotes that the drug has taken effect. In the markedly keratotic hard type of ordinary verruca vulgaris this phenomenon may not always be seen. In most cases, from one to three days after the first injection there has been either a complete cessation or a marked diminution of pain. The peripheral redness that so often accompanies the painful verruca disappears in from two to seven days. All papillomatous lesions flatten out decidedly after the first injection, and in the plantar or palmar types the surface becomes smoother. If within seven to fourteen days following the appearance of the hemorrhagic center the top of the verruca has not come off or the central portion has not fallen out, the keratotic tissue may be removed to determine whether any activity is still present. In most instances, after a lapse of from fourteen to seventeen days following the initial injection the removal of this hemorrhagic keratotic center reveals an underlying normal appearing epidermis. If after two weeks of further observation an active verrucous tissue is seen, the lesion may be reinjected. Of the ninety-seven lesions, most of them having been treated previously by other measures, eighty-nine were cured, five improved and three showed no improvement. Sixty-seven lesions were of the painful palmar or plantar variety, and eighteen were of the verruca vulgaris type occurring on the dorsum of the hands or feet.

Tuberculous Rheumatism.—Brav and Hench review the literature. As described by its proponents, this condition is a form of polyarthritis, simulating in some cases acute rheumatic fever or in other cases chronic atrophic arthritis but bearing some suggestion of tuberculous etiology. Familial tuberculosis, associated visceral tuberculosis, demonstration of Koch's bacilli in the synovial fluid and in the blood stream, positive results of inoculations of guinea-pigs with joint fluid and in some cases the presence of a typical tuberculous joint before, coincident with or subsequent to the development of polyarthritis have been considered evidence for the diagnosis of tuberculous rheumatism. The condition is thought to be due to a tuberculous toxin from some distant focus, a filtrable virus, an attenuated form of bacilli of tuberculosis or an allergic reaction. Formation of true tubercles, therefore, is not the expected finding and, when such pathologic change is present, a superimposed tuberculous arthritis, rather than the condition of tuberculous rheumatism, is thought to exist. Against the acceptance of the syndrome of tuberculous rheumatism have been arrayed a large number of competent investigators who have argued that there is no adequate clinical method of identifying it, no consistently characteristic roentgen evidence, no

experimental or laboratory evidence in its favor that is not highly controversial, and no consistent demonstration of any characteristic microscopic pathology. A statistical study of a series of 150 cases of acute rheumatic fever and 250 cases of chronic atrophic polyarthritis has revealed no significantly higher incidence of familial tuberculosis or associated visceral tuberculosis than that found in a group of 250 control cases. Of a series of seventy-five cases in which a diagnosis of chronic atrophic polyarthritis had been made and in which the pathologic characteristics of a single joint were determined by microscopic examination of tissue or inoculation of guinea-pigs, eight patients were found to be definitely tuberculous. In each of these the tuberculous identity of the joint was suspected prior to the examination of the tissue or inoculation of guinea-pigs, but the association with multiple arthritis was confusing.

Treatment of Chronic Osteomyelitis.—Bozsán believes that an area of aseptic bone necrosis anywhere in the skeletal system may be treated advantageously by connecting the necrotic segment with an adjacent living segment of bone by means of drill channels. He feels that the formulation of this working principle is fairly justified by the satisfactory results obtained after its application in cases of Legg-Calvé-Perthes disease, osteochondritis dissecans, Osgood-Schlatter disease, intracapsular fractures of the neck of the femur, and slipping and slipped upper femoral epiphyses; in all these conditions aseptic bone necrosis is the main pathologic feature. The spontaneous healing process of aseptic bone necrosis, brought about by any cause, is the substitution of living bone in the place of necrotic bone, effected by the slow penetration of tissue elements and capillaries of the adjacent living bone. The drilling of channels into the necrotic area presents nothing but the breaking of broad avenues to facilitate this invasion by new vessels. While attempting to compare the characteristic features of aseptic bone necrosis and necrosis in the wake of septic processes, such as suppurative osteomyelitis, the author has come to the conclusion that, in spite of the seemingly great discrepancies, in the last analysis no difference exists. The clinical and experimental observations of Bancroft on hematogenous osteomyelitis demonstrated that the substitution process is just as active in the recovery of these septic necroses as in the aseptic necroses. This circumstance, rather than the supposed attenuation of the infection, is the reason, in the author's opinion, for the good results obtained from the simple drill hole evacuation of chronic bone abscesses recommended by Brickner. Since the natural healing process in both aseptic and septic necrosis appeared to be analogous, it seemed possible that septic necrosis might respond favorably to the treatment that was found effective in aseptic necrosis. Therefore the author induced substitution and revitalization of necrotic areas of bone in chronic osteomyelitis by connecting these areas with living bone segments by means of saw cuts and drill channels. The procedure in the first two cases—observed one and three-fourths years and one year after operation, respectively—proved successful.

Operation for Delayed Union in Fractures.—Carter describes an operation for delayed union or nonunion in fractures which is based on the principle of drill holes proposed by Beck of Kiel. The procedure consists of boring a number of small holes through the fragment ends, across the line of fracture. This gives rise to a certain amount of hemorrhage, allows the penetration of new blood vessels and furnishes fresh bone pulp, thus creating a stimulus to new bone formation. The author has employed the method in five cases: one of fracture of the shaft of the femur, two of fracture of the tibia and two of fracture of the forearm. It is his opinion that, in those fracture cases with delayed union or nonunion for which no cause can be found which would indicate definitely some other form of treatment, the simplicity and harmlessness of this procedure warrant giving it a trial before resorting to open operation. When the drilling is properly done, the risk of infection is negligible and prolonged hospital confinement is unnecessary. If the treatment is successful, roentgenographic evidence of callus formation will be seen in from three to five weeks; if not, open operation can be performed then. The

only contraindication to the performance of the drilling is an open, infected fracture.

Treatment for Fracture of Olecranon.—Rombold presents a technic for suture of a fracture of the olecranon. The skin incision extends from 2 inches distal to the olecranon to 5 inches proximally, and it is curved either laterally or medially to avoid the olecranon. The skin and subcutaneous tissue are reflected widely, exposing the ulna, the fracture, the olecranon and the triceps tendon. The old clot is cleaned from the fracture. The shaft of the ulna is drilled one-half inch distal to the fracture and well in front of the posterior cortex. Two strips of triceps tendon one-fourth inch wide and 3 inches long are used for the suture of the fracture. The proximal ends, the edges and the muscle-apposed surfaces are freed, and their insertions at the lateral and medial surfaces of the olecranon are left intact. The lateral strip is passed through the drill hole from the lateral to the medial surface and the medial strip is passed from the medial to the lateral surface. They are then tied to each other and sutured through the knot after the fractured fragments have been fixed snugly in position. The wound is closed in layers. The arm is carried in a sling for a week to ten days. Use up to the point of pain is encouraged after four or five days. Four patients have been operated on with perfect functional results.

Dementia Paralytica.—Robards and Tate believe that all cases of constitutional syphilis that do not respond to treatment within six months should be regarded as potential dementia paralytica cases, and, as soon as any involvement of the nervous system is noted the cerebrospinal fluid should be examined. The cerebrospinal fluid should be examined eighteen months after treatment, though it may be negative at that time. It should be examined again six months later. The fact that in dementia paralytica the globulin never disappears and the gold curve seldom regains a normal level indicates the necessity of periodic examinations of the spinal fluid. In syphilitic infected patients of the authors' hospital, dementia paralytica occurs most frequently in Negro men, white women, white men and Negro women in the order named, showing a pronounced increase in the Negro male. Tryparsamide with mercury and bismuth compounds is in all probability the most satisfactory form of therapy. Approximately twenty-five injections of tryparsamide produce clinical improvement. Serologically the effect on the cell count is rapid, frequently reaching normal after twenty injections. Induction of tertian malaria by direct injection of the blood from an infected person is probably the most satisfactory form of fever therapy. It should be used only in institutions. Diathermy and other physical methods of inducing fever are producing encouraging results in some institutions. The authors consider the use of sulphur the most practical method for the induction of fever in instances in which patients are not hospitalized. In patients that do not respond to treatment its continuance hastens death.

Patch Tests in Arsphenamine Sensitization.—Robinson made patch tests with the arsphenamines in 163 persons, twenty-two of whom were nonsyphilitic controls, fifty-four were syphilitic patients, all of whom had received or were receiving arsphenamine treatment without reaction, eighteen were syphilitic patients who had developed a previous postarsphenamine jaundice, and sixty-nine who had had a previous postarsphenamine dermatitis. Tests were made with a 30 per cent solution of neoarsphenamine. Tests were also made with two other arsenical drugs now under investigation as to their therapeutic activity in syphilis. Pieces of old sterile linen about 2 cm square were soaked in the various solutions and applied to the skin while wet, and each was covered with a piece of cellophane. This in turn was sealed at the margins with narrow strips of adhesive tape. Most of the tests were observed twenty-four hours later. All patients were instructed to report any reactions occurring before or after the regular observation time. Results were read as negative when the skin underlying the square of linen was normal or only slightly reddened, as moderately positive if there was erythema and swelling with an occasional papule, vesicle or both, and as strongly positive if there was an acute dermatitis with marked erythema, swelling and vesiculation. Of the twenty-two normal individuals used as controls, patch tests were negative in fourteen, moderately positive in five and strongly positive in three. Two of the three latter persons were tested a second time nine months later, with negative results in both. Of the fifty-four syphilitic patients, forty-three were completely negative, and eight showed moderately positive and three strongly positive reactions. The eighteen patients who had had a previous postarsphenamine jaundice without dermatitis were tested as a further control measure, in all the results were negative. In the sixty-nine patients who, during the course of arsphenamine therapy, had reacted with mild, moderate or severe exfoliative dermatitis, fifty-five were negative and fourteen gave a positive test, but only eleven of these were strongly positive. To four members of this group who reacted with strongly positive patch tests from 0.1 to 0.2 Gm of neoarsphenamine was purposely administered intravenously. All developed a mild to moderate generalized dermatitis. From these observations the author concludes that in a patient who is known to be sensitive to arsphenamine a positive patch test with neoarsphenamine is of no practical value for the determination of persistence of sensitization, since it is sometimes negative in the continuation of treatment.

Irradiation Cataract.—Milner states that exposure of the eyes to the effects of x-rays or radium is likely to result in the formation of cataract. This cataract has a typical appearance, its characteristics being the formation of vacuoles, cloudy areas and later a plaque. It also has a constant situation—the posterior cortex of the lens. There is always a latent period between exposure and cataract formation, and this can be said to be at least two years. It may be many years. One course of high voltage x-rays is sufficient to cause cataract. Too few cases of cataract due to radium have been seen to dogmatize, but it may be said (1) that beta rays, applied at short intervals for short periods, are effective in treatment and harmless to the lens and (2) that gamma radiation is likely to produce cataract. Protection of the eyes during treatment is impracticable, but efforts should be made to devise some method of screening the lens without jeopardizing the effect of the radiation.

Carcinoma of Prostate.—James and Matheson discuss unusual manifestations encountered during an investigation of fifty cases of carcinoma of the prostate: 1. In a case of prostatic carcinoma with perineal involvement, in view of the previous history of periurethral abscess it is probable that an alteration in the tissue planes predisposed to this peculiar feature. General metastases apart from the involvement of the regional lymph nodes was absent. The diagnosis of the perineal node presented no difficulty. It is conceivable that a periurethral abscess might give rise to somewhat similar appearances. 2. In one case, six months after admission, several nodules appeared in the skin over the lower half of the abdomen and one nodule in the skin of the left side of the forehead. Histologic examination of sections of these nodules revealed the typical appearances of carcinoma of the prostate. Tissue predilection in all probability accounts for the rarity of skin involvement. The wide separation of the skin metastases in the case would indicate that they were of hemic origin. 3. Involvement of lymph nodes was illustrated by one case, in a man 61 years of age, who, on admission, was found to have involvement of each inguinal group. Urinary symptoms had been in existence for eighteen months. The left cervical group of glands became palpable three weeks after admission, and six weeks later those in the left axilla became affected. Within a month the glands in the right axilla were enlarged, and later the epitrochlear glands and those in the right supraclavicular region. In the meantime all the glands in the groin had become involved, and a secondary deposit in the left orbit had produced a marked proptosis. Necropsy revealed involvement of all internal groups of glands with diffuse carcinosis of the thoracic duct. 4. Bone metastasis was revealed in a man of 72 who was admitted for a fluctuating swelling the size of a small orange in the middle of the shaft of the right tibia. The radiating spicules in a roentgenogram, together with the evidence of bone destruction and the short history of two months, led to a diagnosis of osteogenic sarcoma. The prostate was small, indurated and nodular. Difficulty and occasional retention of urine with frequency had been present for a few weeks. Section revealed a hemorrhagic cystic tumor

involving the medulla and cortex of the bone, and histologic examination presented the features of a prostatic cancer. This was confirmed at necropsy. No other bones were involved.

***Alcaligenes Faecalis* as Organic Nucleus in Renal Calculus.**—Stuart and his associates report a case of renal calculus with *Alcaligenes faecalis* occurring in the urine and acting in the capacity of an organic nucleus. The organism was proved on intraperitoneal inoculation to be nonpathogenic to white mice and to guinea-pigs. It was inactive as a urica splitter and failed to support Rovsing's theory of stone formation. Autovaccine accelerated the healing of the operative wound, and the authors believe that it shortened the period of convalescence.

Epidural Spinal Abscess: Case. J. Mintzman.—p. 593.

Chorionic Carcinoma.—Thomas reports a case in which a ruptured tubal pregnancy, removed by operation, was followed within a short time by malignant disease of the chorion. Three months after operation the growth had become palpable above the pelvic brim and was found at the second operation to have involved the whole of the right broad ligament, the right pole of the uterus, the bladder and the pouch of Douglas. The symptoms were pain of the lower part of the abdomen, cachexia and a tumor in the right iliac fossa. There was no uterine bleeding or discharge. Two massive doses of high voltage roentgen therapy resulted in definite retrogression of the tumor, considerable lessening of pain and improvement in the general condition of the patient. The author believes that there are three possible ways in which the case can be explained. In considering them he keeps in mind that he is dealing with a gestation sac that had ruptured into the peritoneal cavity. The possibilities are as follows: 1. During the rupture chorionic elements may have been sprayed over the surrounding parts, especially the right broad ligament and the pouch of Douglas. These underwent malignant degeneration later. 2. Chorionic carcinoma may have begun to develop before the actual rupture took place, with the result that malignant cells were directly spread over the broad ligament and the pouch of Douglas. 3. This type of growth extends by way of the veins. Although scattering of malignant cells may not have taken place, the veins of the broad ligament may nevertheless have been packed with syncytial and Langhans' cells spreading in all directions. These would have gone on proliferating after the removal of the ruptured ectopic gestation. An earlier stage of this condition would appear to have been present in Hartz's case.

*Nutritional Anemia of Infancy: Comparison with Chronic Microcytic Anemia of Women During Child-Bearing Period. R. E. Steen.—p. 527.
What Is the Hyoid Apparatus? H. C. Wilson.—p. 535.

Nutritional Anemia of Infancy.—Steen compares the nutritional anemia of infancy with the chronic microcytic anemia of women during the child-bearing period. Nutritional anemia of infancy tends in certain infants to develop about the sixth or seventh month of postnatal life and may persist into the second year. One factor in its development is that milk, whether

human or cow's, is deficient in iron. As a result of this deficiency the store of iron is insufficient to carry the infant through the period until a mixed diet with foods containing iron are added. He demonstrates that etiologically the two anemias have fundamental points in common. An anemia due to a deficiency of iron (i. e., of the hypochromic type) may arise when the iron store in the body is depleted either by direct reduction, e. g. from hemorrhage and infection, or by insufficient ingestion of iron, either as a result of a deficiency in the diet or as a result of defective absorption from the intestine. If idiopathic hypochromic anemia is considered first on these lines, the first etiologic factor in its production must be depletion of the iron reserves from the constant repeated hemorrhages of menstruation and childbirth. No other view can explain why the disease is almost confined to the female sex, to the child-bearing period of that sex, and to the latter half of this period. The hemorrhagic factor in women, however, is liable to be overlooked because it is physiologic. The second etiologic factor must be the dietetic one: a deficiency of iron in the ingested food. The third etiologic factor may be achlorhydria. If the nutritional anemia of infancy is considered on similar lines, the first of the same three etiologic factors is not so obvious at first sight. Reduction of the iron reserves of the infant may occur in a number of ways, which are for the most part antenatal and hence result in a nondevelopment of the iron store of the fetus rather than in its depletion from hemorrhage, as in the case of idiopathic hypochromic anemia. The second etiologic factor is a deficiency of iron in the ingested food, since breast milk contains small amounts of iron and cow's milk still less. This factor will act most strongly in infants who have been kept too long on a milk diet exclusively. The third etiologic factor from the analogy with idiopathic hypochromic anemia might be ascribed to achlorhydria, but Parsons has shown that achlorhydria is not necessarily present in cases of nutritional anemia in infancy; it plays no part in its treatment, when iron alone is specific, and therefore is unlikely to play any important part in its etiology. This maintains the analogy with idiopathic hypochromic anemia, in which achlorhydria is probably of minor importance. The author suggests that, if this view of the synergic action in the production of idiopathic hypochromic anemia in adults and the nutritional anemia of infancy is accepted, and the deduction that fundamentally they are the same, it should help toward a clearer conception of the deficiency anemias as a whole. Furthermore, it would suggest that the present terminology of these anemias might be reviewed. Therefore the author submits the term idiopathic hypochromic anemia and suggests that it be reserved for a disease peculiar to women, just as the term nutritional anemia of infancy is reserved for a disease peculiar to infancy or early childhood, and that such diagnosis should be made only when all other possible organic causes have been excluded.

Diagnosis of Diabetic Coma.—The diagnosis of diabetic coma ordinarily involves no difficulty, but there are cases with some of the signs missing or with complicated phenomena that interfere with the diagnosis. Labbé and Boulin mention two cases that showed the typical symptoms and signs of diabetic coma except for negative diacetic acid reactions (Gerhardt's

test) at the moment of coma. The test became positive after insulin treatment had been applied and finally disappeared after sufficient insulin had been administered. They report another case in which a young diabetic patient without previous evidence of renal disease fell suddenly into coma. The first impression was that this was a diabetic coma, but although the urine showed sugar, it contained no acetone or diacetic acid. Combined with the absence of air hunger and the presence of a myosis, the question of a uremic coma arose. The alkali reserve was extremely low and the blood urea confirmed the existence of uremia. Up to this point it was possible to say only that there was an acidotic coma, but whether of renal or diabetic origin was unknown. In spite of the administration of 920 units of insulin the patient remained in coma and this fact apparently confirmed the absence of diabetic coma.

Treatment of Phlebitis by Infiltration of Sympathetic.—Leriche and Kunlin report three cases of phlebitis treated by injection of procaine hydrochloride into the lumbar sympathetic. The needle is inserted 3 cm. from the spinal line and must pass under or over the transverse apophysis coming against the vertebral body. The needle is then drawn back 1 cm. and inclined at such an angle that the point loses contact with the bone. It is then reintroduced 2 cm. at a less oblique angle until a new bony contact is established. At this point, 10 cc. of a 1 per cent solution of procaine hydrochloride is injected. Usually this injection is painless. If the right location has been found, the patient soon states that there is a warmth of the corresponding leg. Objectively, this warmth may be corroborated. In the three cases of phlebitis thus treated there was a rapid disappearance of the painful sensations and there seemed to be a definite shortening of the duration of the phlebitis. It is necessary to repeat the injection daily as long as there is fever, pain or progressive edema.

Pathogenesis of Albuminuric Retinitis.—Magitot and Dubois discuss the known factors of the pathogenesis of albuminuric retinitis. These are grouped around two pathogenic theories, the toxic and the vascular. They believe it is probable that, when one decreases the volume of interstitial fluid by repeated removals of cerebrospinal fluid, the transudation of the capillaries is reduced at the same time as the reduction of the venous stasis. The authors conclude that the retinitis of generalized hypertension is not of renal origin. Generalized arterial hypertension itself is solely the result of a vascular disease affecting all the vessels. This hydrostatic element can of itself engender ocular lesions. The intracranial hypertension plays an important but not unique part. It seems necessary to postulate a combination of retinal arteriolar lesions, local arterial hypertension and intracranial hypertension in order to realize retinal lesions—edema, hemorrhages, exudates. Although these conclusions result from the observed facts, it is nevertheless necessary to reserve complete evaluation of the pathogenic mechanism.

*Blatomycosis of Lungs and Pleura: Case. A. Spreng.—p. 879.
Evolution of the Conception of Gonorrhea. A. Franck.—p. 881.

Goiter with Solitary Metastasis in Retroperitoneal Lymph Node.—Doepfner relates observations that were made during the course of the necropsy held on a diabetic woman, aged 44, who died following mastoidectomy. He describes the condition of the thyroid, the brain, and a cystic nodule found in the retroperitoneal connective tissue. At first it was assumed

that the retroperitoneal nodule was a cystic lymphangioma, but histologic examination disclosed a struma nodosa colloides. Thus it was assumed that it was a metastasis of an adenoma of the thyroid. However, neither the macroscopic nor the microscopic examination of the thyroid disclosed a primary tumor, but the author suggests that the primary tumor may have been so small that it was overlooked. The localization of the solitary metastasis was unusual, for the adenomas of the thyroid usually metastasize by way of the blood stream. If metastatization does take place by way of the lymph vessels, the metastases are usually in the cervical, mediastinal and bronchial lymph nodes. The author believes that in the reported case the fact that the patient had had diabetes and her age were of some significance. He points out that an adenoma of the thyroid metastasizes rarely in younger persons but that the incidence of such metastases increases greatly during the fifth decade of life.

Blastomycosis of Lungs and Pleura.—Spreng relates a case of pneumomycosis in a woman, aged 53, who had nursed her daughter, who died of acute miliary tuberculosis. Soon after the death of the daughter the patient exhibited a number of symptoms indicative of tuberculosis and her disorder was at first diagnosed as such. However, the sputum, after standing for awhile, had a yeast odor, and in dextrose cultures the yeasts soon overgrew all other micro-organisms, and the case was now diagnosed as blastomycosis of the lung. The sputum contained a few streptococci but no tubercle bacilli. Later a pleural exudate developed. The chest was punctured and the punctate contained yeasts, and thus the diagnosis of blastomycosis of the lungs and pleura was corroborated. Since medication with potassium iodide and roentgenotherapy of the lungs did not produce the desired therapeutic effects, the daily administration of increasing doses of quinine was instituted. Later an autovaccine was prepared and the patient was given intracutaneous injections of from 0.2 to 0.3 cc. of this vaccine at intervals of from two to three days. Under the influence of this treatment the patient recovered. A source of infection could not be determined. The pathogenic agent belonged to the genus of *Saccharomyces*, but exact identification did not succeed. The author points out that the pathogenic yeasts are generally found among the wild yeasts, of which there exist approximately 500 different types. Buschke's classification of pathogenic yeasts differentiates three groups: (1) true yeasts (*Saccharomyces*) the originators of the European blastomycoses, (2) yeastlike micro-organisms, the originators of American blastomycoses, and (3) *Endomyces*, the causes of thrush. In discussing the port of entry the author points out that in a large percentage of cases the primary disease is in the lungs. The presence of diabetes favors development, and in some diseases the yeasts cause superinfections.

Ascoli's Serum Reactions in Neoplasms.—Vercesi and Guercio studied the effects of three tumor serum tests proposed by Ascoli in ninety-seven cases presenting benign and malignant tumors and normal and pathologic pregnancies: 1. In the first test, 1 cc. of clear serum taken from a fasting patient is placed in a tube and to this is added 1 mg. of bilirubin. The mixture is left to stand for an hour and then vigorously shaken. It is centrifugated for fifteen minutes at 300 revolutions per minute. The serum turns yellow, while in the bottom of the tube there remains some bilirubin in excess; the supernatant fluid is poured into another tube containing 1 cc. of ether and the mixture is shaken twenty times and left standing for two hours. If the reaction is positive, the ether turns yellow and there is jellification of the underlying serum (++ reaction); sometimes the ether becomes yellowish and the underlying serum is still fluid (+ reaction). 2. For the acidimetric determination of the ethereal extract of serum and ricinoleic acid, 1 cc. of serum is put in a tube in which 0.2 cc. of an alcoholic solution of ricinoleic acid in the proportion of two per thousand has been

previously allowed to evaporate and it is left standing for a few hours. The serum dried at room temperature on filter paper is extracted in sulphuric ether for twenty-four hours; the ether is decanted and evaporated in a hot water bath. The residue is dissolved in 10 cc. of 99 degree alcohol and titrated with hundredth normal solution of sodium hydroxide. 3. For the glycolytic test *in vitro*, the erythrocytes are washed in a physiologic solution two or three times and 0.4 cc. of erythrocytes is placed in a tube. To this is added 1.6 cc. of Ringer's dextrose solution; after three or four hours of contact, the mixture is centrifugated and the amount of lactic acid in 1 cc. of Ringer's solution is estimated. In these three tests applied by the authors, 80 per cent of the serums derived from malignant tumors gave positive reactions; the bilirubin test by itself was positive in 90 per cent. In serums derived from benign tumors, especially from fibromyomas, the bilirubin test was positive in 50 per cent, while the acidimetric and glycolytic tests were constantly negative. Cases of pregnancy always gave a negative reaction to the acidimetric and glycolytic tests. Of twenty cases, there was only one positive reaction to the bilirubin test, in a case presenting early pregnancy complicated by compensated cardiopathy.

Reaction for Diagnosis of Tuberculosis.—Lenzi advocates the following technic for the diagnosis of pulmonary tuberculosis: Four tenths cubic centimeter of a freshly prepared solution of 3.8 per cent sodium citrate in distilled water is placed in a syringe. With the same syringe, 1.6 cc. of blood is aspirated from the median vein of the arm. The mixture in the syringe is shaken and twenty drops of it is placed in one watch glass and twenty drops in another. One drop of a 1:10,000 sterilized solution of tuberculin is added to the second glass. The contents of each glass are poured in separate tubes, which are placed in a stand. The stand is put in an incubator kept at body temperature, and the millimetric readings of the erythrocytic sedimentation speed are made every ten minutes. The period of observation may be from less than one to two hours. The first tube acts as a control for the second, in which the reaction takes place. In twenty healthy persons the reaction was positive in two, doubtful in one and negative in seventeen. Of thirty-six nontuberculous patients having such diseases as tumors, arthropathies, malaria, exophthalmic goiter and other acute infections, three showed positive, two doubtful and thirty-one negative reactions. Of fifty-eight patients having pulmonary tuberculosis in various stages, fifty gave positive and six negative reactions. The author concludes that his reaction is of great value for the diagnosis of pulmonary tuberculosis, that it may indicate the degree of organic reactivity and of defense, and that in the future it may prove to be an aid to the serologic diagnosis of diseases other than tuberculosis.

Paralysis After Repeated Serum Injection.—According to Hahn, paralysis has been observed after a single injection of serum, but repeated injections, particularly of prophylactic tetanus antitoxin, are the most frequent cause of anaphylactic reactions. He gives the history of a man, aged 38, who, in a motorcycle accident, sustained a wound of the supra-orbital rim. He stated that he had not received a serum injection before. He was given an injection of tetanus antitoxin. During the following night he suddenly felt a burning pain under both scapulas, his chest felt constricted, and he had dyspnea, vomited and developed a wheal exanthem over the entire body. After medication with calcium, the manifestations disappeared withi

the next two days, but six days later he again had burning pains under both scapulas and in the right supraclavicular cavity and he complained of nausea and dyspnea. On the following day he lost consciousness, the wheal exanthem reappeared, he was no longer capable of lifting his arms sideways, and the movement of the head toward the right side was difficult. Examination at a later date revealed hyperesthesia of the right supraclavicular fossa, impairment of the abduction and of the lateral elevation of the right arm, protrusion of the right scapula, and atrophy of the deltoid muscles. Roentgenoscopy revealed elevation of the diaphragm on the right side. The patient had a paralysis of the anterior serratus, of the deltoid muscle and of the right half of the diaphragm. The related nerves, the long thoracic, the axillary and phrenic nerves, originate in the cervical and brachial plexus. The author maintains that this is the most frequent localization of the paralysis following serum injection. The paralysis is usually dissociated in that not all muscles innervated by the same root are equally involved, and the sensory fibers are likewise hardly ever involved. A new careful anamnesis revealed that the patient had received an injection of tetanus antitoxin while wounded during the war. Four years after that he was in a mine accident and was again given a tetanus antitoxin injection. At this time he developed painfulness in the scapulas and impairment of the movement of the arms, which persisted for several months. The attack of paralysis that has been described developed thirteen years after the mine accident. Thus it was the second and third injections of tetanus antitoxin that caused a polyneuritic paralysis.

Replacement of External Malleolus by Free Tibial Transplant.—Noetzel points out that, as a rule, the free tibial transplant is used for the bridging of bone defects, in the form of a rivet or a splint, so that both ends of the transplant are again connected with bone tissue. Rarely does the transplant serve as a substitute for the termination of a bone. The author describes two operations in which the free tibial transplant was used in this manner. In the first case the malleolus and about 4 cm of the fibula had to be removed on account of a myxochondroma. This piece of bone was replaced by a free tibial transplant, 9 cm long and 3 cm wide. The tip of the transplant was forced into the medullary cavity of the fibula in such a manner that the periosteal surface was on the outside. Thus the transplant was securely fastened and the tendons of the peroneus were secured in the proper position behind the transplant by means of catgut threads. Following suture of the wounds, the extremity was put into a plaster-of-paris cast, which was left on for four weeks. Roentgenoscopy after six months revealed that the bone connection was tight and that the transplant had become considerably thicker. The function was satisfactory. The anterior deviation of the transplant caused no disturbances. The case is interesting from the biologic point of view because of the preservation and the independent growth of a transplanted piece of bone, which is connected with the normal bone only at one point and which at the periosteal surface is covered only with skin. The author stresses that whenever possible he takes the transplant from the same leg on which the operation is performed. In the second case the second metacarpal of the right hand had to be removed on account of an enchondroma. It was replaced by a free transplant from the right tibia, 5 cm long and 1 cm wide. Here again the functional results were satisfactory.

Iodine and Cholesterol Content of Blood and Its Relation to Essential Hypertension.—Burger and Mobius found that the age of a person seems to have an influence on the iodine content of the blood. In women it shows a certain

increase after the fifth decade of life. Patients with hypertension as a rule have a greater quantity of iodine in the blood. Increase in the basal metabolism and hyperiodemia, together with the clinical aspects of hypertension, indicate a causal connection between increased thyroid activity and essential hypertension (disturbance in the correlation of excretory organs). The cholesterol content of the blood of patients with hypertension is not increased. The values detected by the authors were generally within normal limits, and they think that the occasional appearance of high cholesterol values in patients with hypertension is of no causal significance.

Influence of Vitamin C on Dopa Reaction.—Gruneberg and Schade call attention to Schroeder's report on the inhibition of the dopa reaction by vitamin C, *Klinische Wochenschrift* (13:553 [April 14] 1934, abstr. *THE JOURNAL*, June 9, 1934, p 1902) and then describe their own studies. Tests on tissue sections revealed that vitamin C (cevitamic acid, or ascorbic acid) inhibits the dopa reaction. They assumed, however, that the cevitamic acid does not attack the dopa oxydase in the tissue sections but merely causes chemical transformations in the dihydroxyphenylalanine and thus makes it unsuitable for one reaction. They were able to prove this in another series of tests, in which tissue sections were exposed to the influence of vitamin C for thirty minutes, then the vitamin C was completely removed by repeated washings, and after that the sections were exposed to dopa solution in the same manner as several control sections. The reactions were the same, that is, there was no inhibition of the dopa melanin formation. They admit that test tube experiments can be employed for the clarification of biologic problems only to a limited extent, but they nevertheless believe that their experiments are not without value in the investigation of the relations between vitamin C and pigment formation, and they think that their observations justify the conclusion that, if vitamin C influences pathologic pigmentations of the skin, it is not the dopa-oxydase that is the point of attack.

Takata Reaction in Liver Diseases.—Schindel and Barth performed the Takata test in 687 cases. Of this number, fifty-nine gave a positive, twelve a weakly positive and 616 a negative reaction. They believe that the positive Takata reaction is characteristic for cirrhosis of the liver, for it was positive in 83.8 per cent of the cases. When the liver was impaired as the result of a circulatory disturbance, the Takata reaction was positive in 18 per cent of the cases. A similar percentage of positivity of the Takata reaction was found in the disorders that are grouped under the heading of hepatopathies. In cholestopathies and in cholangiopathies the percentage of positivity was still smaller. Patients with tumor metastases in the liver had a positive reaction rather frequently. In other diseases the Takata reaction is only occasionally positive, and, if it is, an involvement of the liver may be assumed. The authors show that the outcome of the Takata reaction is caused neither by a shifting in the albumin-globulin quotient nor by a change in the total albumin content of the serum and that there is no parallelism to the sedimentation speed of the erythrocytes. The positive Takata reaction indicates a disappearance of the hepatic parenchyma, and it is thus an indication of morphologic changes. It has not been determined what degree of parenchymal damage is necessary to make the reaction positive. It is likewise still unknown in what manner the liver effects a change in the flocculation behavior of the serum. The authors are inclined to believe that the appearance of the lower forms of the fatty acids plays an important part. The outcome of the Takata test gives no information about the functional condition of the remaining parenchyma, and for this reason the tolerance tests of the liver cannot be dispensed with. When the tolerance tests are carried out it is necessary to give attention to the previous diet, for the authors believe that disregard of this factor is the cause of many divergences in the estimation of the tolerance tests. There is rarely a parallelism either between the Takata reaction and the tolerance tests or between the different tolerance tests. The authors' own experiences with the galactose and bilirubin tolerance tests did not make them less pessimistic about the value of the tolerance tests, but they gained the impression that at least the Takata reaction presents a valuable addition to the diagnostic armamentarium, although only a small proportion of liver diseases can be definitely detected with it.

Value of Ventriculography and Encephalography.—

Urban applies the term ventriculography to that form of roentgenography of the brain in which the air is introduced directly into the ventricles, and he designates as encephalography that form in which the air is introduced by suboccipital or lumbar injection. He concludes that they are the most valuable of the physical aids for the diagnosis of cerebral tumors. Since the filling of the ventricles is of vital importance for a correct diagnosis, ventriculography is sometimes effective in cases in which encephalography fails. The introduction of air has therapeutic value, particularly in genuine and traumatic epilepsy. The author asserts that improvement or cure is effected in about 55 per cent of the cases of genuine and traumatic epilepsy in which air inflation is combined with medication by means of bromine derivatives or phenobarbital.

Intermittent Dilatation of Abdominal Aorta.—Hogler

points out that intermittent dilatation of the abdominal aorta is often overlooked or mistaken for other abdominal disorders, such as gastric or duodenal ulcer, cholelithiasis, chronic appendicitis or various vascular disturbances (atherosclerosis, aneurysm, or Pail's abdominal vascular crisis). Rosenbach was the first to give a detailed description of the disorder (1894), but later several other authors described it. Rosenbach gave the following description of the clinical aspects. Without apparent reason, and occasionally in a state of complete well being, a brisk pulsation appears in the epigastric region, accompanied by more or less severe pains. The patients state that it feels as if they had a second heart in the abdomen, the pulsation of which causes a burning and piercing pain. This pain frequently radiates to the back and rarely also to the thighs. In addition to this there develop colic-like gastro-intestinal disorders accompanied by heartburn, nausea and urge to defecation and occasionally constipation and flatulence. Frequently the patients complain of severe hunger, palpitation of the heart and profuse sweating. The attacks of pain may last several hours and they usually appear at intervals of several weeks. Palpation reveals a whirring sound over the abdominal aorta. The vessel is noticeably dilated and usually sensitive to pressure. On auscultation over the pulsating abdominal aorta the examiner hears a long drawn out blowing sound, which is loudest to the left of the median line between the edge of the liver and the umbilicus. As the pulsation and the pains subside, the objective manifestations disappear likewise. It is assumed that these peculiar symptoms are the result of the dilatation of the abdominal aorta and the dragging on the adjoining organs, particularly the ganglions and the nervous plexus. Moreover, the intense pulsations influence also the adjoining sections of the gastro-intestinal tract. The underlying cause is presumably a vagus neurosis, which by reflex action reduces the tonus of the abdominal aorta and is followed by a dilatation of the vessel. The author presents the clinical histories of several patients with intermittent dilatation of the abdominal aorta. Periods of latency alternate with attacks. During the latent periods the author was able to produce attacks by means of the subcutaneous injection of from 0.5 to 1 mg of epinephrine. Tests

on normal persons revealed that in these the symptoms of dilatation of the abdominal aorta remained absent following epinephrine injection. Thus epinephrine injection may prove valuable in differentiating dilatation of the abdominal aorta from other abdominal disorders.

Phrenic Pressure Point in Diseases of Gallbladder.—

Bayer calls attention to a sign that, although described before, has been given little attention. The sign is helpful in the differentiation of disorders of the gallbladder and liver from ulcers of the stomach and the duodenum, the latter frequently presenting symptoms similar to those of hepatobiliary disorders. The sensitive point on the phrenic nerve is between the sternocleidomastoid muscle and the anterior scalenus on the right side of the neck. If disease of the diaphragm and of the thoracic cavity can be excluded, the painfulness of that point to pressure indicates disease of the gallbladder, but absence of sensitivity does not necessarily prove the absence of gallbladder disease.

Diathermy in Hypertension.—Trolow and his associates

are of the opinion that disturbances in the endocrine-sympathetic systems with subsequent regulatory disturbances of the entire vascular system and with vascular spasms of the abdominal organs play an important part in the pathogenesis of essential hypertension. They decided to apply diathermy to the celiac plexus and to the suprarenals. The position of the kidneys was determined and marked on the skin. Two electrodes, each 150 sq cm in surface, were fixed in such a manner that one half of each electrode was applied over the marked region and the other half reached beyond it into the region of the suprarenals. In addition to these two electrodes a third, of 300 sq cm, was applied in the center of the epigastric region, immediately below the xiphoid process. In some cases this third electrode was replaced by two, each of them having half the surface and being placed over the lateral epigastric regions, below the costal arch. The treatments were given with a current strength of from 0.5 to 2 amperes. The patients were lying down when the diathermy was applied. The treatments lasted from five to ten minutes, and they were given daily or every second day. The total number was from fifteen to thirty, depending on the results. After each treatment the patients had to rest for about thirty minutes. The blood pressure, the pulse, the respiration and the general condition were determined before, during and after each treatment. Of the twenty-five patients treated in this manner four were not influenced, one showed a slight increase in pressure, but the other showed a reduction of the maximal pressure. The minimal pressure was reduced in fifteen cases. The reduction of the pressure that had been obtained by means of the diathermy persisted in some instances for from eight to ten months, while in others a relapse occurred after about two months. In two patients the blood pressure was higher three or four months after the treatment than it had been before. The frequency of pulsation and respiration remained generally about the same. The authors conclude that in the majority of cases the results were favorable and think that the treatment deserves further attention.

*Interruption of Pregnancy on Account of Pregnancy Pyelitis Really on Account of Pyelonephritis F von Mikulicz Radecki—p 2264

"Pyelitis Granularis" as Cause of Hemorrhage from Renal Pelvis.—Ottow and Pahl say that although granular pyelitis has been known for a long time, the number of cases that have been observed is small. Aside from cases accidentally discovered at necropsy, granular pyelitis is usually detected in the course of renal surgery for severe renal hemorrhages. They give the history of a woman, aged 34, who had had hematuria of changing severity for ten weeks. Cystoscopy revealed that the bladder and ureters were free from pathologic changes. Pyelography showed certain abnormalities that made

the existence of a neoplasm possible, and surgery was resorted to. The kidneys were practically normal, but the wall of the renal pelvis was thickened and there were several ridge-like protrusions. On palpation the mucous membrane was rough, and examination through the magnifying glass disclosed that it was stippled. In the connective tissue there were bloody streaks and spots, some of them being overfilled vessels and some being extravasations. Microscopic inspection of the capsule revealed funnel-like inflammatory foci, which were old interstitial inflammations. The uriniferous and the vascular apparatus of the kidney was largely intact. The severest changes were in the connective tissue of the renal pelvis. Underneath the epithelial layers of the mucous membrane there were leukocytic and lymphocytic infiltrations and lymph follicles. In some places the epithelial layers were lifted up, particularly above the follicles, but also occasionally above the infiltrations. The chronic inflammatory process led to ruptures of the vessels in the region of the renal pelvis and perhaps also in the kidney and thus led to prolonged hematuria, which in turn resulted in anemia. The authors think that decapsulation of the kidney is not likely to arrest hemorrhages caused by granular pyelitis and that extirpation will generally become necessary.

Interruption of Pregnancy on Account of Pyelitis.—In cases of pyelitis of pregnancy in which the renal parenchyma becomes involved, that is, in pyelonephritis, von Mikulicz-Radecki considers interruption of the pregnancy advisable. On the basis of statistics, these cases amount to from 1 to 3 per cent of the total material. He thinks that in pyelitis limited to the renal pelvis conservative measures usually produce improvement and cure. The danger begins when the renal parenchyma becomes involved, particularly when the involvement is bilateral, when the accumulation of pus in the renal pelvis has become so great that it acts like an abscess and when the upper portion of the ureter has become involved to such an extent that as a result of the fixation of the ureteral bent the discharge of urine and pus is obstructed. The author thinks that the danger is especially great for women with an infantile or asthenic habitus. He recommends a trial with conservative measures, particularly ureteral catheterization, irrigation of the renal pelvis and continued drainage of the ureter. However, if these measures do not improve the condition soon, the pregnancy should be interrupted. Interruption is indicated (1) when fever and pains persist for longer periods and when chills and accelerated pulsation become manifest, (2) if toxic and septic symptoms develop (icterus, vomiting and loss of weight), (3) if the conservative measures fail, and (4) if the albumin content of the urine exceeds the content in leukocytes and when casts are present. In discussing the technic of the interruption of pregnancy he states that some authors have advised against the vaginal route because of the danger of infection by colon bacilli. He believes that this danger has been exaggerated. He advises the vaginal method as long as the fetus is not yet viable and recommends prompt evacuation of the uterus by anterior hysterotomy, so that there is no time for the micro-organisms to travel upward. However, if the fetus is already viable, the author considers delivery by abdominal section the best method.

Osteochondritis Dissecans.—Hellström and Östling report seventy-three cases of osteochondritis dissecans, of which forty-six were of the knee joint, twenty-four of the capitulum humeri, and one each of the talus, the second metatarsal head and the second metacarpal head. The last mentioned localization has not been described in the literature. Bilateral disturbances were present four times in the knee joint and twice in the elbow joint. Patients with osteochondritis dissecans of the capitulum

humeri, the patella and the lateral femoral condyle were, as a rule, of younger age than those having osteochondritis dissecans of the internal femoral condyle. Most patients belonged to the working class. The symptomatology has not differed from the ordinary one. It is noteworthy that locking may occur without free bodies being present. The diagnosis was confirmed by roentgen examination. This may show typical osteochondritis dissecans in which no such condition can be discovered by arthrotomy. The differential diagnosis is concerned with specific and septic osteochondritis, spontaneous traumatic separations, chondromalacia and so-called aseptic bone necrosis. In considering the course of the disease, one has to pay attention to the origin and subsequent development of the osteochondritic focus, the loose bodies and secondary articular changes, especially arthritis deformans. The authors show that osteochondritis dissecans may arise as a direct sequel of a single trauma and they are on the whole advocates of a traumatic etiology without, however, underrating the constitutional and hereditary factors. Osteochondritis dissecans may conceivably be concerned with two forms, the purely traumatic and the spontaneous form, the true cause of which is still unknown. As to the frequency of osteochondritis dissecans of the elbow joint, the authors have examined the roentgenograms of 1,500 elbows and roentgenologically both elbow joints of 206 male subjects who did not present any symptoms. Osteochondritis dissecans of the elbow joint has occurred much less frequently in their material from Stockholm than in Nielsen's material drawn from the rural districts of Jutland.

Acute Pancreatitis.—Mikkelsen deals with severe acute pancreatitis. A review of the literature shows that its treatment still remains almost exclusively operative and that the results of such treatment still show an average mortality of 50 per cent. The operative treatment involves an attack either on the pancreas (incision into the capsule and drainage) or on the bile ducts. The author points out that there is no anatomic basis for an operative attack on the pancreas. The pancreas has no true capsule in the anatomic sense of the term. The structure that is divided on incision into the pancreas in the peritoneum covering the organ, and an incision through this peritoneal covering cannot relieve its secretory tension. The pancreas is made up of many small lobules that are separated by thin septums of connective tissue each enclosing an individual lobule. In order to relieve the pressure tension in the pancreas it would be necessary to divide the thin layer of connective tissue covering each lobule and that would not be feasible. Besides, these interlobular connective tissue septums are intimately connected with the glandular tissue, which is always affected at the same time. An operation of this kind is thus apt to cause an increase rather than a reduction in the necrosis and intoxication; besides, it implies a not inconsiderable risk of hemorrhage and fistula formation. The theoretical basis for an operation on the bile ducts is more logical, but the systematic employment of such operative measures in recent years has not lowered the case mortality decidedly, no doubt because these patients are in such a poor condition that they are not able to stand any operative treatment whatever. Recently a few surgeons have turned to a more conservative treatment, some of them postponing the operation till the "shock stage" is passed, others waiting until all acute symptoms have subsided, after which an operation is performed for gallstones when such are found to constitute the underlying cause of the acute pancreatitis. Operation is also performed, of course, if the process goes on to abscess or cyst formation. During the last eight years they have treated conservatively thirty-nine patients with severe acute disorders of the pancreas. Twenty of these were extremely ill, their general condition being very poor (shock). Three of the twenty patients died, and the remaining nineteen were gravely ill but not actually shocked. The diastase value was most often 3,000, 4,000, 6,000 and 12,000. In but two cases was the diastase value under 2,000. Operation was performed only in cases in which gallstones were ascertained and not until from one to three weeks after the acute symptoms had subsided. The treatment adopted by the authors consisted of a supply of fluid by mouth, skin and vein, and the use of stimulants and peristaltics. The mortality with this conservative treatment was 7.5 per cent.

THE OCCURRENCE AND TREATMENT OF NEUROLOGIC CHANGES IN PERNICIOUS ANEMIA

S. M. GOLDHAMER, M.D.

F. H. BETHELL, M.D.

RAPHAEL ISAACS, M.D.
AND

CYRUS C. STURGIS, M.D.

ANN ARBOR, MICH.

In recent years with the advent of a potent medication for the treatment of the anemia of pernicious anemia, a great deal of consideration has been given to the effect of liver and desiccated stomach therapy on the associated lesions of the spinal cord and brain in this disease. Innumerable workers have reported, with considerable diversity of opinion,¹ the results of their investigation concerning the progression and prevention of nervous system involvement. Our purpose in this paper is to present a study of a comparatively large group of patients, extending over a period of seven years, concerning the occurrence of neurologic and mental manifestations in pernicious anemia and to determine the effect of various types of antianemic therapy on them.

The group consisted of 461 patients with pernicious anemia observed at the Simpson Memorial Institute between the years 1927 and 1934. Comprising this group were 261 men (56.6 per cent) and 200 women (43.4 per cent), ranging in age from 20 to 80 years. Of this total, 408 (88.5 per cent) patients are still alive and fifty-three patients (11.5 per cent) are dead. Table 1 lists the age and sex distribution of those patients who are still living. The general admission ratio between all men and women at the University of

Michigan Hospital is, however, approximately the same as that of the pernicious anemia group, and this may account for the difference in the latter group.

Regardless of the age group, nervous system involvement has been noted in 364 of the 408 patients (89.2 per cent). Of this group, 43.2 per cent had the symptoms of cord changes at the onset of the disease, and in the remainder (46 per cent) the changes developed at some period during the course of the illness, but before the patient came under our observation. Posterior column manifestations, including numbness and tingling of the hands and feet, were present in 89.2 per cent of the patients. Evidence of involvement of the lateral column was noted in 41.6 per cent and combined degeneration in 40.7 per cent. In a series of fifty of these patients, especially studied by Dr. George Hammond of our clinic, cerebral symptoms occurred in 64 per cent.

In table 2 are listed the relationship between the age, the sex, the clinical manifestations of pathologic changes of the cord, and the red blood cell count when the patients were first observed by us. Apparently the occurrence of cord manifestations is independent of the state of the blood and may occur at any age. Furthermore, from table 3, it is obvious that the earliest evidence of the disease may be an alteration of the nervous system that precedes the development of the anemia. Also, it is apparent that a severe anemia may be present without evidence of spinal cord changes. It is suggestive, moreover, from this table, that there is a slightly greater tendency for cord changes to develop at the onset of the disease in women than in men, as this occurred in 48.8 per cent of the former and 37.6 per cent of the latter.

A series of fifty cases was selected at random and studied intensively in order to determine the occurrence of various individual neurologic symptoms and signs (table 4), which might indicate involvement of the nervous system. These observations were made by various members of the staff during routine examinations. The importance of the frequency of such symptoms and signs as numbness, tingling, ataxia, impaired vibratory sensation, hyperactive reflexes, irritability and bladder disturbances is most evident.

A second series of fifty cases was selected by Dr. George Hammond with the specific idea of determining the frequency of all the possible neurologic manifestations listed by Tilney and Riley (table 5). The striking features in this group are the wide variety of manifestations of disease of the spinal cord and the frequency of mental changes,² which have not received

as much emphasis in the literature. Evidence of cerebral involvement was noted in 64 per cent of the cases. This varied from very mild irritability to severe mania. Cerebral manifestations may be present alone or in association with cord disturbances, they may be present with or without any evidence of anemia, and they may present themselves as the earliest and only manifestation of pernicious anemia.

To determine progression of cord changes with treatment in pernicious anemia, three factors may be

TABLE 1—Age and Sex Distribution of the Pernicious Anemia Patients Studied in this Group

70-79	20	11	31
Total	211	177	388

considered. First, the majority of patients have at least slight evidence of cerebral involvement; therefore evaluation of subjective information is often difficult, and some doubt must be cast on a statistical study based solely on data of this character. Second, only exaggerated variations from the normal can be listed in an arbitrary manner, as there is no exact method by which subjective information may be recorded. For example, as shown by Piercy,³ Gray⁴ and others, the threshold value of vibratory sensation varies in individuals. Various test points have different values; the vibratory sensation is less pronounced as one grows older, although never entirely absent, and the results depend

been instituted. This finding has been explained by many investigators as being due to the fact that symptoms and signs of central nervous system involvement may exist without the presence of demonstrable pathologic changes of the cord. These facts must be given serious consideration when conclusions are drawn regarding the benefits derived from the various types of therapy. Furthermore, it must be emphasized, as Ahrens¹ and other observers have noted, that there may be spontaneous variations in the intensity of the neurologic manifestations, and thus all conclusions regarding the effect of treatment must be made with caution.

For the purpose of classification, a level of 4 million red blood cells per cubic millimeter has been selected arbitrarily as the dividing line between those patients who had received a reasonable amount of treatment and those in whom treatment had been obviously inadequate. Included in the latter group are: (1) those who took too little treatment or none at all, and (2) those who did not respond to the usual dosage of antianemia therapy, which would have been sufficient for most patients.

The average duration of the disease in the entire group of patients before admission was about two years. Although the general clinical impression has been that there is a definite correlation between the duration of illness before treatment and the prognosis, our observations do not support this view conclusively. Of 126 adequately treated patients in the male group, when first observed by us, eleven had no demonstrable cord lesions, sixty-one had posterior column involvement, one had lateral tract degeneration and fifty-three had combined degeneration (table 6). Of the

were improved in twenty-three following treatment, they were unchanged in twenty-three and accentuated in five. In no instance were the signs improved; in forty-two they remained the same, and they progressed in five. In two patients no further observations were made following treatment.

Of a total of sixty-nine cases inadequately treated among the males, (table 6), thirteen presented no evidence of spinal cord changes when first observed. Eleven of these developed neurologic manifestations during the course of this inadequate therapy and two

did not. Of thirty-eight cases of posterior column degeneration, the symptoms improved in five, remained the same in twenty-one and were progressive in twelve. In the same group of cases, the signs regressed in one instance, remained unchanged in twenty-one and progressed in fifteen. In the eighteen instances with combined degeneration, the symptoms improved in two, remained unchanged in eleven and became worse in five. The signs did not improve in any of the cases of this group; they were unchanged in eleven and progressed in five.

In the group of eighty-one female patients who were adequately treated (table 6), seven had no evidence of

terior column degeneration, the symptoms improved in twenty-one, remained unchanged in seventeen and became worse in one. In the same group the signs

improved in none, were constant in eighteen and progressed in two. In thirty-five patients with combined degeneration, the symptoms improved in fifteen, were constant in nineteen and were worse in one. In the

same group the signs improved in none, remained stationary in thirty and were progressive in one.

In a group of fifty-seven female patients inadequately treated, cord changes developed in one during the period of observation and did not develop in three; no further data were obtained. Thirty of these patients had posterior column degeneration. Of these, the symptoms improved in three, remained unchanged in fourteen, and became worse in eleven. In two cases, no further data were available. In the same group

patients. One other fact worthy of mention is that the lower extremities are affected more often than the upper ones, and improvement is less common in them. This fact may possibly be related to the relatively greater length of the tracts supplying the legs as compared to those leading to the arms.

Table 8 shows the prognostic relationship between cord lesions and the various types of antianemic therapy given in adequate and inadequate amounts. It appears that fresh liver and intravenous liver extract

TABLE 6.—*The Effect of Adequate and Inadequate Therapy on the Spinal Cord Lesions in the Male and Female Series*

there was no improvement in the signs; in seventeen cases they remained unaltered, and in twelve the signs progressed. Of nineteen patients with combined column degeneration the symptoms improved in two, remained unchanged in twelve and became worse in three. In none of these cases did the signs improve; in fifteen they remained stationary and in three they progressed. These observations suggest that there is a better prognosis when only the posterior tracts are involved than when combined tract degeneration is present and that improvement can be expected more often in symptoms than signs resulting from the spinal cord lesions.

In table 7 are listed the total number of patients (males and females) in the various age groups with cord signs and symptoms and their status following adequate and inadequate therapy. With adequate therapy the symptoms improved in 49 per cent, remained the same in 39 per cent and became worse in 12 per cent. The signs improved in 2 per cent, remained the same in 83 per cent and became worse in 15 per cent. With inadequate therapy, improvement of symptoms occurred in only 16 per cent, remained the same in 49 per cent and became worse in 35 per cent. The signs improved in 2 per cent, remained stationary in 59 per cent and became worse in 39 per cent. A comparison of the two groups in table 7 demonstrates most satisfactorily the advisability of giving adequate therapy for the blood, because of its secondary effect on the central nervous system. It cannot also be stated, however, that the antianemic treatment has a specific curative effect on the spinal cord degeneration but rather aids in the general feeling of the well-being of the patient. In this indirect way, at least, antianemic treatment contributes to the improvement in the manifestations in the central nervous system. Further, our observations would suggest that with adequate therapy there is a more favorable outlook for improvement in the neurologic involvement in younger

are somewhat superior to desiccated stomach and liver extract orally, in the treatment of the neurologic manifestations, but the number of cases is entirely too few to form a basis for definite conclusions. These figures again serve to illustrate the value of giving sufficient treatment for the anemia and its secondary effect on the spinal cord lesions.

Of the total of 461 patients, 11.5 per cent have died, of whom thirty were men and twenty-three women.

The age limit of the group was 30 to 80 years. At the time of admission, the red blood cell counts ranged from less than one million to five million per cubic millimeter. Twenty-four of these patients, or approximately 45 per cent of the group who have died, had cord symptoms at the onset of the disease, and in an additional twenty-two, or 41 per cent, they developed before entrance to the hospital. Of this entire group,

56 per cent followed treatment as prescribed. Eleven patients died in the hospital and necropsies were performed on ten of them. All but one showed widespread combined degeneration of the spinal cord, and this patient had, in addition to pernicious anemia, carcinoma of the gallbladder, with no evidence of spinal cord involvement either clinically or at necropsy. As far as could be determined by correspondence, the cause of death could not be ascertained in fourteen cases. Of the remaining twenty-eight patients, seven-

2. Clinical evidence of spinal cord changes has been noted in 89.2 per cent of the cases and cerebral symptoms in 64 per cent.

3. Regardless of the type of adequate antianemic therapy, improvement in symptoms of the central nervous system was observed in less than 50 per cent of the cases, and improvement in signs in about 2 per cent of the cases.

4. Antianemic therapy, when given in sufficient amounts, does not have a specific curative effect on

teen were known to have been confined to bed before death because of progressive cord changes. The others died as the result of pneumonia, cardiac failure, nephritis and accidents (table 9).

The importance of complications in pernicious anemia cannot be overemphasized because of their unfavorable influence on the prognosis. The most common complications are trophic ulcers, lung infections and genito-urinary infections. Of the ten cases in which necropsies were performed, 73 per cent showed genito-urinary involvement clinically and 82 per cent at necropsy. Over 70 per cent of patients coming to postmortem examination had multiple gangrenous areas over the buttocks and heels. The presence of these complications is nearly always indicative of a terminal stage of the disease.

We have evaded the question of peripheral neuritis⁵ occurring in pernicious anemia, as neuropathologists are not in agreement as to its existence. If it does occur, its presence in relapse and its disappearance with treatment may well account for the subjective improvement that is so frequently noted.

SUMMARY AND CONCLUSIONS

1. A series of 461 cases of pernicious anemia have been studied to determine the occurrence of neurologic manifestations and to observe the effect of various types of antianemic therapy on them.

5. In addition to Ahrens,¹ Baker, Bordley and Longcope,² these include:

ferent individuals, and clinically there are slow and rapid types.

6. Such complications as genito-urinary infection, trophic ulcers and pneumonia, when present in association with marked central nervous system degeneration, are usually indicative of a poor prognosis.

Urologic Triumphs.—I might go on indefinitely through a long list of urological triumphs: the cystoscopic destruction of bladder tumors, the cystoscopic removal of ureteral calculi, the early recognition and cure of kidney cancer, conservative kidney surgery. The recognition of the nature of many vague abdominal syndromes which have been variously treated and mistreated until such time as a careful urological survey has demonstrated the underlying factors and removed them. However, the only point which I wish to make with this very sketchy review is that medicine and surgery have kept step with the rapid onward progress made in other lines and that urology, in spite of its youth, has contributed its full quota.—Rathbun, N. P.: Urology: Retrospect and Prospect, *J. Urol.* 32:417 (Nov.) 1934.

THE TREATMENT OF CHRONIC HEMOLYTIC JAUNDICE WITH LIVER EXTRACT

EDWARD C. REIFENSTEIN, M.D.

AND

ELLERY G. ALLEN, M.D.

SYRACUSE, N. Y.

While chronic hemolytic jaundice is an interesting clinical entity, medical textbooks contain little detailed information concerning the disease and consequently many physicians are not thoroughly familiar with the condition. Some authors mention that chronic hemolytic jaundice is a rare disease, while others state that it is relatively common; in fact, Lee¹ makes the statement that the increasing literature indicates that it is actually more common than pernicious anemia, and it is possible that this startling declaration is true when one considers that mild atypical types of chronic hemolytic jaundice exist.

Two types of the disease are generally described, the congenital and the acquired. The former is more generally diagnosed, whereas the acquired type more frequently escapes recognition. Failure to diagnose the acquired type of the disease may be attributed to the unfamiliarity of physicians with the condition. Some authorities claim that there is a definite acquired type of chronic hemolytic jaundice, while others, especially Gänsslen,² dispute the point and maintain that the manifestations which appear in later life are but expressions in a case with an inherited constitutional hemolytic defect. Whether or not the latter is an adequate explanation, the term "acquired hemolytic jaundice" is justifiable if it but suggests to the observer the necessity for detailed studies of the blood and careful search for etiologic factors in jaundiced patients. In chronic hemolytic jaundice, such studies may reveal an increased icteric index, urobilinuria, a variable degree of anemia (possibly of a microcytic type), reticulocytosis, increased fragility of the erythrocytes to hypotonic sodium chloride solution, indirect van den Bergh reaction, notable absence of bile in the urine, and clay colored stools. In our experience we have observed such instances even in the absence of splenomegaly. Enlargement of the spleen, although difficult at times to detect, is not invariably demonstrable and unfortunately certain observers have refused to consider chronic hemolytic jaundice unless this abnormal finding is present. In our opinion the milder types of the disease may fail to show splenomegaly, and we feel that the failure to demonstrate it should not adversely influence the opinion when laboratory evidence indicative of dissociated jaundice is obtained. We have seen such instances in which there was an elevated icteric index, urobilinuria, microcytic anemia and increased fragility of the red cells without evidence of splenomegaly and in which no cause for the condition could be ascertained. It is probable that many such mild cases exist in which satisfactory explanation as to cause is lacking and many observers, particularly Krumbhaar,³ have pointed out

that the exciting cause in the acquired types cannot always be determined.

With regard to the treatment of the condition, splenectomy has long been considered to be the most successful accepted therapeutic procedure and in the majority of instances the results have been most gratifying. It is generally agreed that, although marked clinical improvement usually follows splenectomy, the resistance of the erythrocytes to hypotonic sodium chloride solution remains disturbed. Another point of interest is that following splenectomy occasional cases have been reported in which the hemolytic crises have recurred. The occasional therapeutic failures after splenectomy have been cited as arguments against the concept that the spleen is the primary cause of the disease. Because of these failures and because patients rarely die from the disease and, as one author states, "they are more jaundiced than sick," many clinicians have adopted a conservative attitude and have felt that splenectomy should not be done if the patient is not incapacitated by the disease. The mortality with splenectomy is reported to be about 3 per cent.

In certain instances this may influence the opinion against surgery, or conditions may be present which

Chart 1 (case 1).—Erythrocyte and hemoglobin determinations from 1929 to 1934 during intervals of liver extract therapy, Extralin therapy and when no liver extract was given.

might make surgery inadvisable so that other methods of treatment may be necessary. In November 1929 one of us (E. C. R.) advised the use of liver extract for a patient having an acute crisis of chronic hemolytic jaundice because of the similarity of chronic hemolytic jaundice to pernicious anemia in relapse. The patient improved markedly in strength and appearance and at that time a surgeon advised against splenectomy. The patient, therefore, continued to take liver extract without medical supervision. In 1928, Ordway and Gorham,⁴ giving the same reasons for using it, first successfully used liver extract in the treatment of chronic hemolytic jaundice and stated that the idea was original with them. However, they declared that Minot⁵ in 1928 used liver extract in a case resembling acquired hemolytic jaundice and that following treatment the reticulocytes decreased rather rapidly and the red blood cell count returned to normal. In 1929 Lepehne⁶ suggested the administration of liver (from 200 to 250 Gm.)

daily or liver extract in the less severe cases without marked crisis or anemia. In 1931 Neuburger⁷ reported two cases in which liver extract was used and in which there followed no improvement in the anemia; hemolysis was not diverted, and the jaundice did not decrease. In the same year Jedlička and Várodí⁸ used liver extract in three similar cases without good effect—either subjectively or objectively—and in one case, during treatment, increasing jaundice and more obvious splenomegaly developed.

Chart 2 (case 1).—Temperature, pulse and respiration rate when no treatment other than liver extract was given.

The conflicting evidence in the literature justifies further studies as to the value of liver therapy in chronic hemolytic jaundice. Therefore we present the summary of our experience with this form of therapy in three such cases.

REPORT OF CASES

CASE 1.—A. M., a boy, aged 14, seen by E. C. R. in consultation with Dr. Adelbert Marsh, Nov. 2, 1929, complained chiefly of weakness, vertigo, fulness in the left upper quadrant of the abdomen, jaundice, and fever of three days' duration.

The patient's mother was well. The father had had recurrent attacks of jaundice since childhood and at the present time has gallstones and his erythrocytes show an increased fragility to hypotonic sodium chloride solution. His sister had had recurrent attacks of jaundice since childhood. A recent test for the reaction of her erythrocytes to hypotonic sodium chloride solution revealed normal results.

Chart 3 (case 1).—Fragility of erythrocytes to hypotonic sodium chloride solution.

In childhood the patient had mumps, measles and at 7 years of age pneumonia with otitis media. The tonsils were removed at 9 years of age. Since 6 years of age he had had recurrent attacks of fever and jaundice with vomiting without abdominal pain. These attacks would occur every two to three months and be of about one week's duration.

The present illness began, Oct. 31, 1929, with vertigo and weakness. His parents noted a peculiar yellow of his skin. The temperature was elevated to 104.5 F. He did not vomit. There was neither sore throat nor coughing. The urine and stools were dark. The temperature remained elevated, between 101 and 103, and when I saw him two days later it was 102 F. At that time he complained of a peculiar, full, pulling sensation along the left costal margin.

Physical examination revealed jaundice, pallor of the mucous membrane of the mouth and tongue, and an enlarged tender spleen extending to the umbilicus. At the University Hospital the following studies were made: hemoglobin 8.5 Gm., erythrocytes 3,150,000, white cell count 5,050 (chart 1). The differential count was normal. There was a variation in the size of the red cells. Free hydrochloric acid was found in the gastric secretion. The urine was strongly positive for urobilin. The icteric index was increased. There was increased fragility of the erythrocytes to hypotonic sodium chloride solution. The initial hemolysis began at 0.52 per cent and was complete at 0.38 per cent (chart 3), and the diagnosis of chronic hemolytic jaundice was made. Because of the similarity of pernicious anemia, one vial of liver extract-Lilly was prescribed orally, three times a day. This therapy was followed by definite improvement, so that at the end of a month the patient felt stronger, the red blood count had risen to 4,150,000, and the hemoglobin to 10.5 Gm. (chart 1). A surgical consultant at that time advised against surgery. The patient continued to take three vials of liver extract daily without medical supervision for eighteen months and felt well, having had no attacks during the latter period. Liver was then discontinued and later he consulted an osteopath because of a recurrence of symptoms.

Chart 4.—Temperature, pulse and respiration rate in case 2.

May 18, 1932, ten months after the liver had been discontinued, he was readmitted to the University Hospital because of mental confusion, prostration and fever. Three days prior to admission he was suddenly seized with vomiting. He became markedly jaundiced, had a temperature of 104 F. and was seen by Dr. Marsh, who referred him to the hospital. There was marked evidence of dehydration, definite jaundice and a temperature of 104 F. The spleen was very tender and extended to the umbilicus and nearly to the crest of the ilium. The examination of the blood at that time revealed erythrocytes 1,415,000, hemoglobin 5 Gm. (Haden-Hausser) (chart 1), white blood count 2,475, volume index 0.922, volume per cent 11.5, icteric index 18. The urine was strongly positive for urobilin. No bile was found in the urine. The stools were dark brown. The blood Wassermann reaction was negative. Three cubic centimeters of solution liver extract-Lilly (derived from 15 Gm. of liver) was given intramuscularly daily for ten days and then one vial of liver extract-Lilly powder given orally three times a day. At the end of a month the blood count was as follows: erythrocytes 3,545,000, hemoglobin 10.5 Gm. (Haden-Hausser) (chart 1), white cell count 7,000, the differential count normal. The patient's strength returned and he has been free from complaints from that time until the present. He has continued to take liver extract-Lilly by mouth and has had no recurrence of the attack. However, during the fall of 1933, on the advice of a friend, he began to take four capsules of Extralin three times a day instead of one vial of the powdered liver extract three times a day. In February 1934 his parents noted that his color was not as good as formerly. Examination of the blood at that time revealed erythrocytes 3,510,000, hemoglobin 11.5 Gm. (Haden-Hausser) (chart 1), white blood count 8,700, volume index 1.022, volume per cent 31.5, icteric index 30, differential count normal, and reticulocytes 5.0 per cent. In the fragility test hemolysis began at 0.50 per cent and ended at 0.38 per cent (chart 3). Three

8. Jedlička, V., and Várodí, S.: *Ztschr. f. klin. Med.* 118: 286, 1931.

cubic centimeters of Lederle solution liver extract parenteral refined and concentrated (derived from 100 Gm. of liver) was given at weekly intervals, with a definite improvement in the patient's appearance and strength. The red blood count and hemoglobin have improved. The indirect van den Bergh reaction, the icteric index, and the size of the spleen have remained unchanged. Repeated studies of the erythrocytes for evidence

of increased fragility to hypotonic sodium chloride solution have revealed a persistent diminished resistance of the cells. There was no agglutination of the patient's cells by his serum with the Widal, Abrami and Brulé test.

The serum cholesterol was 67 mg.

CASE 2.^o—Mrs. R., aged 31, an Italian housewife, admitted to the medical service of the University Hospital, Sept. 5, 1933, complained of severe epigastric pain, radiating

urine for urobilinogen and bile after institution of liver therapy were negative. Fragility tests, September 27, showed the initial hemolysis at 0.48 per cent and complete at 0.37 per cent (chart 5). October 20, the icteric index was 12 and the indirect van den Bergh test showed a faint positive reaction. November 6 the blood cholesterol was 160 mg. and the icteric index 8. November 13 the following observations were made: red cell count, 5,240,000; hemoglobin, 16 Gm.; white cell count, 5,950; normal differential count; reticulocytes, 1.2 per cent. The spleen was palpable two fingerbreadths below the costal margin; the liver was not palpable. There was no jaundice.

She was discharged from the hospital November 19 and readmitted Jan. 30, 1934, complaining of nervousness and pain in the left upper part of the abdomen. One week before she had had tonsillitis and had had no liver extract for two weeks. On examination the patient was suffering acutely from severe pain in the upper part of the abdomen, the throat was slightly reddened, the temperature was 101.8 F., the pulse 110 and the respiration rate 32; there was no apparent icterus, and the spleen was palpable and tender. The red cell count was 4,100,000, the hemoglobin 78 per cent (Sahli), white cell count 9,300, with a normal differential count. The urine was positive for urobilin in a dilution of more than 1 to 20; there was no bile. Liver extract (3 cc. concentrated) was given February 1 and thereafter once a week. Subsequent to one injection of liver extract, urobilinuria disappeared and on February 7 the red cell count was 4,510,000, the hemoglobin 12 Gm. February 20, a mild attack of complicating obstructive jaundice developed; the icteric index rose to 19, bile was present in the urine, the van den Bergh test showed a faint immediate direct reaction. There was no agglutination of the patient's cells by her serum with the Widal, Abrami and Brulé test. The patient was discharged from the hospital, March 14, feeling well; the icteric index was 9. Intramuscular liver extract (3 cc. concentrated) was prescribed to be given once a week at home. On May 20 the patient reported that she had had none of her former symptoms since her discharge from the hospital, two months before, and that she was better than she had been for a year.

CASE 3.—Mrs. K., aged 41, Polish, admitted to the University Hospital Jan. 13, 1934, complained of pain in the upper part of the abdomen of six months' duration.

The family history and marital history were irrelevant. The patient was born in Poland and had come to this country one year before. Dec. 8, 1933, she was admitted to the University Hospital because of vague pain in the upper part of the abdomen and obstipation. At that time the physical examination was negative except for a firm tender mass in the left

upper quadrant, considered to be spleen. She was given an edema, felt relieved and signed her release before adequate studies could be made. No parasites or ova were found in the stool.

The present illness began in July 1933, at which time she first noted epigastric distress, made worse by eating. Occasionally during the past two or three months she had had a "yellow color," frequently had noted chills and passed dark colored urine.

Chart 6 (case 3).—Fragility of erythrocytes to hypotonic sodium chloride solution.

slight icterus. The edge of the liver could be palpated and the spleen was definitely enlarged, firm and tender.

Laboratory examination revealed the red cell count 3,775,000, white cell count 7,300, normal differential, volume per cent 30, hemoglobin 11.9 Gm., volume index 0.90, icteric index 20. The van den Bergh test showed a positive indirect reaction. The

Chart 5 (case 2).—Fragility of erythrocytes to hypotonic sodium chloride solution.

to both quadrants of the upper part of the abdomen, of ten days' duration.

The family history was unimportant. The patient was born in Italy, was married at the age of 14 and had given birth to five normal children. Her general health had been good except for the following: In October 1931, at the University Hospital, the gallbladder was removed for chronic cholecystitis and cholelithiasis. At that time no anemia was found, the icteric index was 50 and urobilin and bile were found in the urine. Pain in the upper part of the abdomen continued and she returned to the hospital, July 11, 1932, complaining of nervousness, weakness, pain in the left upper quadrant, and nausea.

Physical examination at that time revealed a palpable, tender spleen. The icteric index was 35, the red blood count 3,740,000, hemoglobin 72 (Sahli), reticulocytes 0.5 per cent, and white blood count 6,250, with a normal differential. Sedimentation time was one hour and seven minutes. Fragility tests of the erythrocytes failed to show any definite abnormality. Other laboratory studies, including blood and spinal Wassermann tests, urine, gastric analysis, cystoscopic examinations, pyelograms and gastro-intestinal roentgenograms, gave negative information.

She improved on a liberal diet, iron and rest in bed. She refused an exploratory examination and was discharged after six weeks with no anemia, an icteric index of 15 and a palpable spleen. The diagnosis of hemolytic jaundice was considered but not definitely proved.

For ten days prior to this entry the patient had noted severe epigastric pain radiating to both upper quadrants of the abdomen, nausea, belching of gas and, on one occasion, vomiting.

Physical examination showed temperature 101 F., pulse 90, respiration rate 22 and definite icterus. There was marked tenderness without spasm over the epigastrium, the spleen was palpable three fingerbreadths below the left costal margin.

Laboratory examination showed: red cell count 4,540,000, volume per cent 38.5, volume index 0.96, icteric index 15, reticulocytes 1.7 per cent, white cell count 8,000, differential normal, indirect van den Bergh reaction positive, blood cholesterol 90 mg. The urine showed urobilinogen in a dilution of 1 to 30. Initial hemolysis of the erythrocytes began at 0.46 per cent and was complete at 0.39 per cent (chart 5).

Liver extract, 2 cc. (derived from 10 Gm.) daily, was given intramuscularly from September 16 until October 21; thereafter, 3 cc. (derived from 100 Gm.) of concentrated liver extract was given once a week until her discharge, November 27. The temperature approached normal, September 17, and was normal thereafter (chart 4). Sixteen examinations of the

9. The studies in cases 2 and 3 were aided by a grant from the Hendrick's Research Fund of the Syracuse University College of Medicine.

stained blood films showed the red cells to be well filled, presenting, however, a diffuse microcytosis. Fragility tests showed the initial hemolysis at 0.48 per cent and complete at 0.40 per cent (chart 6). The urine was negative except for an increase of urobilinogen. The Ewald test meal revealed normal acid values. No abnormal changes were noted in repeated stool examinations. The blood chemistry was normal except for a cholesterol of 111 mg. The Wassermann and Kahn reactions of the blood serum were negative. There was no agglutination of the patient's cells by her serum with the Widal, Abrami and Brulé test.

The patient was given 3 cc. of concentrated liver extract intramuscularly (derived from 100 Gm. of liver) on February 12 and weekly thereafter. February 17, fragility tests showed initial hemolysis at 0.43 per cent and complete at 0.36 per cent. She improved steadily and was discharged, March 14, without symptoms, although the spleen was still palpable; the icteric index was 7. Twelve days later (March 26) she was readmitted to the hospital, complaining of epigastric pain and vomiting of three days' duration. While at home she had failed to receive one of the weekly injections of liver extract. Examination showed definite icterus; the temperature was normal on admission, rose to 100.6 F. (rectal) on the second day and then returned to normal. The liver and spleen were palpable and tender. The red cell count was 3,592,500, hemoglobin 10.2 Gm., white cell count 8,200, volume per cent 30, volume index 0.94, reticulocytes 4.5 per cent, and icteric index 64. The van den Bergh test gave a strongly positive immediate direct reaction. Smears did not appear remarkable, although occasional microcytes were noted. The urine showed a strongly positive reaction for bile and urobilin. Intramuscular liver extract (3 cc. concentrated) once a week was resumed. A diagnosis of complicating obstructive jaundice was made. March 30 there was no pain or vomiting; the icterus was decreased. No clay colored stools were noted. The icteric index was 23. The van den Bergh test showed a faint immediate direct reaction. The urine gave a faint positive reaction for bile. The fragility test showed initial hemolysis at 0.50 per cent and complete at 0.37 per cent (chart 6). Urobilinogen was strongly positive. Fragility tests, April 20, showed initial hemolysis at 0.50 per cent and complete at 0.41 per cent (chart 6). May 10, the blood counts were as follows: red cell count, 4,800,000; hemoglobin, 13.5 Gm.; white cell count, 10,900.

COMMENT

Three patients with chronic hemolytic jaundice were treated with liver extract. In one case, prior to liver therapy, which was instituted in 1929, an acute hemolytic crisis occurred every two to three months. Since then no crises have occurred except one which happened during a period when liver therapy had been discontinued. While there has been an improvement in the patient's strength, appearance and the anemia, nevertheless the increased icteric index, urobilinuria and increased fragility of the red cells to hypotonic sodium chloride solution have persisted.

In the two other cases an improvement in the patient's strength and appearance was noted and the laboratory studies revealed a disappearance of a mild anemia, urobilinuria and clinical jaundice; the increased fragility of the erythrocytes, however, was essentially unaltered. While we believe that splenectomy offers the most hopeful therapeutic procedure in the more severe cases of chronic hemolytic jaundice in which no causative factors can be demonstrated, it would appear that treatment of such individuals with liver extract may have a beneficial effect. It will be noted that liver therapy was instituted during the acute period of the crisis and that there was definite clinical improvement in the patients. While we feel that liver was of value in these instances, we appreciate the fact that spontaneous remissions do occur and for that reason feel

that more work must be done to prove that liver treatment will actually affect the course of the acute episodes. We suggest that liver extract may be of benefit in those individuals who are unfavorable surgical risks, who refuse operation, or in whom it is decided that the disease is not sufficiently incapacitating to warrant surgical intervention. It is also possible that if surgery is anticipated, or if the patient is in the stage of an acute hemolytic crisis, liver extract may considerably improve the clinical picture and make the individual a better surgical risk or possibly shorten the incapacitating period of the crisis.

SUMMARY

Three cases of chronic hemolytic jaundice were treated with liver extract and all showed definite clinical improvement. In one case, treated since 1929, clinical improvement without recurrence of a crisis occurred during treatment but the increase in the icteric index, urobilinuria and increased fragility of the erythrocytes persisted despite the improvement in the anemia. The two other cases, similarly treated, showed no definite and sustained increase in the resistance of red blood cells to hypotonic sodium chloride solution, but the disappearance of a mild degree of anemia, clinical jaundice and urobilinuria were noted.

It is felt that further observations as to the effect of liver therapy in chronic hemolytic jaundice are necessary before definite conclusions can be drawn. It is recommended that such therapy be given a trial and that careful detailed blood studies be made during the observations, together with similar observations on untreated cases.

THE TREATMENT OF HEMOPHILIA

HAROLD W. JONES, M.D.

AND

LEANDRO M. TOCANTINS, M.D.

PHILADELPHIA

It is 130 years since hemophilia was first observed and accurately described by Otto.¹ The progress in its therapy has been slow and full of disappointments. This report will deal with a review of the methods of treatment of the condition at the disposal of the physician today. It is based partially on observations made on twelve hemophilic patients at various times over a period of seven years.

For the purpose of this discussion, hemophilia is defined as an inherited or noninherited tendency of males to bleed, characterized by the presence of a prolongation of the coagulation and prothrombin time of the venous blood. Cases of hemophilia in which a history of inheritance is not obtainable are included. Five of our patients fall in this group, although four of them have brothers similarly affected. Instances of so-called sporadic hemophilia are about as frequent as those in which a clear-cut history of inheritance can be obtained, which may indicate that the defect is sometimes atavistic.

From the Department of Medicine of Jefferson Medical College.
Prepared under a grant from the J. Ewing Mears Research Foundation.

Read before the Section on Practice of Medicine at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 15, 1934.

1. Otto, J. C.: An Account of a Hemorrhagic Disposition Occurring in Certain Families, *Medical Repository* 6:1, 1803.

The treatment of hemophilia may be divided as follows:

A. Preventive:

1. Prevention of the transmission of the disease.
2. Prevention of the accidents that usually precipitate the onset of a phase of hemorrhage.

B. Treatment of the condition itself:

1. Attempts to influence the general course of the disease or permanently change the fundamental defect of the blood; i. e., the coagulation factors.
2. Treatment of an acute hemorrhagic phase:
 - (a) General.
 - (b) Local.
3. Treatment of complications.

CRITERIA OF IMPROVEMENT

A statistical evaluation of the merits of any form of treatment is almost impossible because of the rarity of the disease. To judge the effectiveness of any measure we feel that the following criteria are useful:

1. Changes in the course of the disease in general may best be gathered from the patient's own history of increase or diminution in frequency and severity of the attacks of bleeding and the acute joint disturbances. Determinations of the venous and capillary clotting time give little idea of the progress of the disease, so they are not of practical use from this standpoint. We have observed patients enjoying comparative freedom from bleeding for six months or longer and yet their venous clotting time was continuously prolonged (two hours or more). On the other hand, it is common to find relatively short, almost normal, venous and capillary clotting times during the acute phase of bleeding.

2. Whenever blood transfusion is used to prepare the patient for a surgical procedure, the venous clotting time may be relied on as an indication of its effectiveness. Capillary clotting time determinations, unless done according to the technic of Gibbs² and Christie,³ are worthless as an index of the blood-tissue reaction in coagulation.

3. During the acute phase, the presence or absence of bleeding and its degree as measured objectively, or indirectly by hemoglobin and red blood cell estimation, should be the only criterion of improvement. In other words, during a phase of bleeding all measures should be directed toward its cessation with or without evidence of control of the blood clotting time. Often too much stress is placed on reducing the clotting time and sight is lost of the fact that measures other than blood transfusion designed to reduce the rate often fail to affect or may even increase the bleeding. Hemostasis, even in a hemophilic patient, is not synonymous with reduction of the coagulation factors to normal levels. During phases of bleeding, other factors, perhaps of a vascular nature, play a part in accentuating the hemophilic individual's tendency to bleed. This is best illustrated by the frequent detection of a prolonged skin bleeding time during these phases. The following case illustrates increased skin bleeding time:

L. M., a hemophilic man, aged 23, was admitted to the Jefferson Hospital on the verge of collapse after a fall. There was a hematoma the size of a grapefruit in the right thigh, and other extensive hemorrhages were noted in both legs. The pulse rate was 140 and of filiform character. The hemoglobin

(Sahli) was 45 per cent, the erythrocyte count was 2,450,000, the platelet count was 488,000, the venous clotting time was thirty-eight minutes; the skin bleeding time was seven minutes and the tourniquet test +. Two days later the general condition was unchanged, the hemoglobin was 35 per cent, the erythrocytes numbered 2,040,000, the platelet count was 360,000, the venous clotting time 172 minutes, the skin bleeding time was six minutes and the tourniquet test +. Three days later the general condition was unchanged, but the hemoglobin was 33 per cent, the erythrocyte count was 1,910,000, the platelet count was 566,000, the venous clotting time was 160 minutes, the skin bleeding time was thirty minutes and the tourniquet test + 4. At the end of four days the pulse was normal, the general condition was good, the hemoglobin was 40 per cent, the erythrocyte count was 2,410,000, the platelet count was 538,000, the venous clotting time was 188 minutes, the skin bleeding time was 1 hour and the tourniquet test + 4. There were only slight changes in these readings for the following three days; the general condition remained good. On the eighth day the hemoglobin was 48 per cent, the erythrocyte count was 2,970,000, the platelet count was 716,000, the venous clotting time was 176 minutes, the skin bleeding time was one minute and the tourniquet test was negative. There was gradual improvement in the patient's general condition and no bleeding occurred from this time on.

PREVENTIVE TREATMENT

Since many of the cases exhibit a clear-cut history of inheritance, the sisters of patients with hemophilia and the patients themselves should be made acquainted with the mechanism of inheritance and told of the great likelihood of their having "bleeders" in the family. The number of children in a family of hemophilic individuals is unusually large. In our series the average number of children born from transmitters of hemophilia was 5.3 (69 per cent male, 31 per cent female); 80 per cent of the males were bleeders. There does not seem to have been any attempt to curb procreation, owing probably to a lack of clear understanding on the part of the hemophilic individuals as to the manner in which the defect is transmitted. The fact that the condition often skips a generation tends to make them incautious and to trust to chance. Birch found that both the individuals with hemophilia and the transmitters seem to have families a little above the average in number.⁴ Furthermore, the transmitters of hemophilia have more sons than daughters, while persons with hemophilia have more daughters than sons.⁴ In this fashion nature appears to make sure of the perpetuation of the disease. Since not all daughters of transmitters are themselves transmitters and there is no known method of detecting them aside from reproduction, the problem of the control of the disease from the eugenic standpoint is a difficult one. All daughters of hemophilic males are carriers and should not reproduce.⁵

PROPHYLAXIS

With the knowledge that the hemophilic individual is more easily affected by trauma than the normal, he should be cautioned against engaging in strenuous occupations or undergoing operative procedures without the proper preparation. It would be well for an individual with hemophilia to carry a document stating clearly the condition from which he is suffering, in order that he may be properly protected if he is rushed unconscious to a hospital or physician's office. This means of identification could be sewed to a prominent part of the inner clothing.

Preoperative Preparation.—If operative intervention is indicated, there are two methods to which one may resort to prevent undue hemorrhage:

1. Preliminary blood transfusion is known to reduce the clotting time for a period of from two to six days. Blalock⁶ performed a successful amputation of the arm in a hemophilic individual, and a cholecystectomy was done in one of the patients in our series after several blood transfusions had been resorted to.

2. Protein sensitization has been advocated since Vines⁷ discovered its effect in increasing the coagulability of the blood. Mills,⁸ Marlow,⁹ Eley and Clifford¹⁰ recommend it. The method consists in sensitizing the patient by intramuscular injection of 3 or 4 cc. of a foreign protein (sheep or hen serum preferably) after the usual preliminary test of sensitivity by intradermal injection of a drop of the serum. Two weeks later one drop of the serum first used is injected intradermally. The appearance of an urticarial wheal indicates sensitivity. Mills found a marked improvement in the blood coagulability and the reaction of the prothrombin to be much more normal especially toward cephalin after this treatment.¹¹ The intradermal injections should be repeated at intervals of several weeks to determine the sensitivity to the protein. This sensitivity usually lasts a year. Eley and Clifford tried the method in eight hemophilic children. They found that the coagulation time of the capillary blood was definitely shortened but that that of the venous blood remained unaltered. They did not consider the treatment to have any value in controlling hemorrhage from the larger blood vessels or in preventing the occurrence of hemorrhagic effusions into joints, subcutaneous hematomas or intestinal bleeding, but they were convinced of the benefit of the method in the prevention or control of bleeding from superficial injuries. It is probable that any beneficial effect brought about by this method comes from changes in the blood vessels. Two of our patients were given this treatment for one year with no significant change in any aspect of the disease.

Weil¹² advises intramuscular injections of 30 cc. of fresh serum one or two days before the operation. Intravenous injection of whole compatible human blood, citrated or noncitrated, one day or a few hours before the operation is just as satisfactory. The intravenous injection of blood has been shown to bring to normal the retarded rate of transformation of prothrombin into thrombin in as short a time as thirty minutes after it is given.¹³ It is therefore important that the blood group of every hemophilic patient should be known and a suitable donor kept available during and after any operative procedure. Throughout the first decade of life, with its many accidents and changes in dentition, these precautions are especially indicated.

Operations in general should be avoided but, when performed, hemostasis should be painstakingly cared for. It is helpful to ligate each piece or section of tissue

before incising it and to use fresh serum to dress the wound. The usual accidents to which children are exposed should be avoided. The operations of circumcision and incision of the frenulum should not be undertaken.

Diet.—Some advise the use of a high protein diet. It has been observed that an increased coagulability of the blood takes place for a period of one to four hours following a meal rich in protein in normal human beings.¹⁴ It has not been demonstrated, however, that this diet is beneficial in hemophilic patients. Kugelmass¹⁵ has observed no changes in the concentration of the clotting substance in patients with hemophilia after a diet high in protein. Neither has any improvement been observed following the ingestion of any of the known vitamins.¹⁶ In our experience high protein or high fat diets have not affected the hemorrhagic phase appreciably.

Purges.—The use of drastic purges is undesirable, and some patients believe that a purge induces an attack of hemorrhage.³ However, Otto¹ recorded the fact that there was a general belief among the hemophilic families he had studied that purging by sodium sulphate was beneficial.

Focal Infection.—The removal of foci of infection is desirable, particularly in view of its effect on the course of the arthritis and in improving the general condition of the patient. That infection bears relationship to the attacks of bleeding is disputable, since many attacks appear in the absence of infection and a number of our patients have gone through acute infections with very slight or no manifestations of bleeding. Dental extractions or other operations should not be attempted, of course, without the proper preparation as described.

Some of our patients have stated that immobilization in bed for long periods of time has increased the hemorrhagic tendency. One patient affirmed that a number of attacks of hematuria lasting several weeks had followed emotional shocks.

TREATMENT OF THE CONDITION ITSELF

By treatment of the condition itself is meant any attempt to change the fundamental defect (the prolonged coagulation and prothrombin time of the blood) or to diminish the incidence and severity of the manifestations associated with the condition. So far we have remained unconvinced of the value of many advocated measures. We have tried a few. Ovarian extract from different makers, in small and large doses, orally and intramuscularly, was used in four of our patients, and no changes were noted in any aspect of the disease. Previous reports of beneficial results following ovarian therapy were not based on the use of proper criteria. The work of recent observers fails to substantiate the claims.¹⁷ So far we must content ourselves to explain the almost absolute limitation of the disease to males on the basis of the laws of heredity, rather than on the hypothetical, disproved¹⁸ assumption

that the defect is present in the female but kept in check by ovarian hormones. Splenic and thyroid extracts were likewise of no immediate or remote value.

Course.—The disease seldom makes its appearance until several weeks after birth, and from then on until maturity the attacks of bleeding occur at intervals, probably more often in the latter half of the first decade. The preference of the hemorrhages for the joints and

Chart 1.—Effect of the administration of two organ extracts to a hemophilic individual (S. M.). There was an interval of at least two weeks between courses. *Plat*, platelets, *V. C. T.*, venous clotting time.

muscles during the developmental period leads to deformities and retardation in growth. If the hemophilic individual reaches the third decade, however, his subsequent course is comparatively safe, as the incidence of attacks of bleeding decreases considerably. The grandfather of one of our patients, known to have hemophilia, died at the age of 60. The venous coagulation time, however, remains unaltered, which again exemplifies the fallacy of using this determination as an indication of the progress of the disease. The disease therefore follows a fairly definite course and its manifestations decrease in severity as the patients grow older. This phase of the present discussion may therefore be dismissed with the statement that there is no method known at present that is of undisputable, permanent value in altering the general course of the disease.

TREATMENT OF AN ACUTE PHASE OF BLEEDING

General Treatment.—Here the therapeutic measure *par excellence* is the transfusion of blood, unmodified or citrated. Sometimes as small an amount as from 30 to 50 cc. is enough to check the bleeding and reduce the coagulation time.¹⁹ It should be stressed again that the index of effectiveness of any measure used in an acute phase is the production of hemostasis and not the changing of the coagulation time. Large hematomas may be produced by punctures of veins during these phases. This can be avoided by the quick application of pressure and its continuation for at least one hour. Too often a hematoma interferes with the use of a vein for a much needed transfusion. Great care should be taken in having the blood cross-matched. Citrated blood is equally efficacious,³ but reactions are more frequent.

The improvement resulting from a blood transfusion lasts between two and six days when given in the usual dosage. In children we have found that intraperitoneal

transfusions are of equal benefit. This method is especially to be preferred when difficulties are experienced with the intravenous method, since the introduction of partially clotted blood may aggravate the symptoms. Intraperitoneal transfusion is not indicated in an emergency arising from hemorrhage. Blood must be transfused into a vein; the absorption of intraperitoneally injected blood is too slow to be helpful.

The intravenous or intramuscular administration of various serums (sheep serum, horse serum, hemostatic serum), autologous blood given intramuscularly, or the use of calcium, ergot, peptone, parathyroid extract, thromboplastic substance or tissue fibrinogen have proved of little value in our hands. Estrogenic substance was given to two of our patients and, like others,¹⁸ we found no changes in the course of the disease following its administration. We suggest that the administration of these drugs in hemophilia should be discontinued, since their use involves delaying the employment of measures of proved value.

If the patient is or has been made sensitive to a certain serum, a small desensitizing dose given intradermally is said to check the bleeding.⁸ We have had no experience with this type of therapy in the acute phase. However, in other hands,³ and even in one of Vines' cases,⁷ it was followed by negative results.

Local Treatment.—The problem of stopping the bleeding is simplified if the area is accessible. Intestinal or urogenital bleeding cannot be treated by local measures. The other commonest sources of the bleeding are in the joints and muscles, from the oral mucous membrane and deep skin cuts. When the bleeding is taking place in the joints or muscles, immobilization of the part is indicated, but the application of icebags and compression is of very little use. The following remarks apply to the control of bleeding in the accessible portions of the body, such as the skin and subcutaneous tissue, and oral, rectal or nasal mucous

Chart 2.—Effect of administration of two organ extracts to a hemophilic individual (L. M.). There was an interval of at least two weeks between courses.

membrane. The measures to be employed may be grouped under the following heads:

1. Pressure is sometimes helpful, particularly when combined with other measures to be specified later. In order to be of any help it must be applied for one hour or longer. This may require special bandages, particularly when the bleeding is in difficult situations, such as in the oral mucous membrane. A "pyramidal" pack (a series of superimposed small gauze layers)

Physiol.* **78**: 500 (Nov.) 1926. Christie, R. V.; Davies, H. W., and Stewart, C. P.: Studies in Blood Coagulation and Haemophilia: Haemic Function in Haemophilia, *Quart. J. Med.* **20**: 481 (July) 1927.

8. The trial of defibrinated blood injected intravenously is indicated.

9. Endocrinotherapy, according to our criteria, has been of no value.

10. Any therapeutic measure that diminishes venous clotting time and does not lessen the bleeding phenomena, or even increases them, should be avoided.

11. The use of special diets has proved disappointing.

12. Intradermal injections of antihuman platelet serum was followed sometimes by a marked decrease of the venous clotting time in three hemophilic patients, two of whom were going through an acute phase of bleeding; no prompt and permanent cessation of the bleeding followed the injections.

13. In an acute emergency due to hemorrhage, intraperitoneal transfusion is not indicated. Blood must be injected into a vein.

1930 Chestnut Street.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRs. GOLDHAMER, BETHELL, ISAACS AND STURGIS, REIFENSTEIN AND ALLEN, AND JONES AND TOCANTINS

DR. ADOLPH SACHS, Omaha: Hemophilia, hemolytic jaundice and pernicious anemia are diseases that have periods of remission and therefore it is difficult to estimate the full value of any form of therapy. Hemophilic patients during their periods of remission, often know without medical aid that they are less liable to bleed. Unless an emergency arises, it is advisable to postpone operative procedures until the patient enters such a remission. I have found that keeping hemophilic patients on a diet rich in vitamins, liver and iron affords the best means of keeping them fit. Mental and physical fatigue should be avoided. These measures will not forestall bleeding, but they give as much promise as any specific therapy thus far offered. Transfusion remains the most efficacious procedure in controlling hemorrhage, but its benefits are evanescent, lasting only from two to six days. Hence it is used only to control hemorrhages or in preparation for an operation. I am interested in the relationship of whole blood iron to whole blood copper. I have shown that, when the whole blood iron decreases, the whole blood copper tends to increase, and vice versa. To date no work on blood iron and copper in hemophilia has been reported. No abnormal relationship between the copper and iron content was present in one case examined. However, the tests were made during a period of remission. I plan to follow these cases during increased bleeding phases. I agree with Drs. Reifenstein and Allen that hemolytic jaundice is more common than the literature indicates. Mistaken diagnoses of gallstones in cases of hemolytic jaundice are commonly made, because 75 per cent of these patients do have gallstones. One of my patients has been on liver and iron therapy and has had no attacks in two years. This form of liver does not contain the factor effective in pernicious anemia, which further demonstrates the difficulty in evaluating any therapeutic response in a disease with normal remissions. It is difficult to determine what form of liver therapy is best suited in each individual case, but most men agree that long and continued use of liver is needed before neurologic changes improve. Patients who stop their liver therapy have relapses, and their neurologic complications soon recur. It is then often difficult to get a second remission. It is interesting to follow the whole blood iron and the whole blood copper in cases of pernicious anemia. As the patient improves, the whole blood iron increases and the whole blood copper decreases. It has been my experience that psychoses improve much more slowly than do the cord changes.

DR. WANN LANGSTON, Oklahoma City: It has been my privilege to follow a case of hemophilia since July 1931, during which time ten distinct plans of therapy have been used with equally unsatisfactory results, except that during a period of administration of theelin, 1 cc. intramuscularly three times a week, the clotting time approached normal and remained so

throughout the period. Theelin daily had no effect on the long clotting time. I make this statement, conscious of the frequent spontaneous remissions which these cases exhibit. My experience is limited to the parenteral administration of liver extract in a small group of cases of sickle cell anemia, in which no beneficial effects were observed. Drs. Goldhamer, Bethell, Isaacs and Sturgis in a study of an impressive group of cases arrive at the conclusion that little improvement in neurologic signs can be anticipated in adequately treated cases of pernicious anemia. My experience with a smaller group has impressed me similarly. It is inconceivable that repair can take place to any considerable extent in the degenerated tracts in the cord. On the other hand, it is conceivable that in the early stages of cord involvement, when perhaps there is only edema of the myelin, adequate treatment may arrest the process or even restore the tracts to normal function. Recently, through the courtesy of Dr. W. F. Keller, I have been privileged to follow a typical case of Addison's anemia with mild posterior column signs. With 46 per cent hemoglobin and 1,900,000 red cells, ten 3 cc. doses of a liver extract concentrate were given parenterally in twenty-seven days, when therapy was discontinued, the hemoglobin being 95 per cent and the red count 5,100,000. During the next month the hemoglobin reached 120 per cent, the red count 6,600,000, and during the following four weeks hemoglobin 123 per cent, red count 7,900,000, together with splenomegaly, encephalopathy, vascular crises, and so on. In spite of this remarkable response on the part of the hematopoietic system, the neurologic signs rapidly increased in severity, although the subjective symptoms almost entirely disappeared. In evaluating the efficacy of therapy in relieving neurologic symptoms, one must distinguish if possible between those caused by actual cord damage and the similar symptoms due to local nutritional disturbance; namely, the paresthesias, weakness, and the like. The latter group responds remarkably to adequate therapy, just as the same symptoms in other anemias respond to proper management.

DR. V. P. SYDENSTRICKER, Augusta, Ga.: The variety of remedies for hemophilia is sufficient proof that none are of particular avail. The important thing brought out by Drs. Jones and Tocantins is the advisability of blood transfusion in the presence of hemorrhagic manifestations. It appears that the citrated blood is more valuable than whole blood. A smaller needle will minimize the probability of a hematoma. The changes of the blood resulting from citration may stimulate coagulation. I should like to ask Drs. Reifenstein and Allen two questions. What was the behavior of the reticulocytes during the period of liver therapy, and was there any indication as to the part played by the liver in this particular dyscrasia? In the series of cases reported by Drs. Goldhamer, Bethell, Isaacs and Sturgis the high incidence of neurologic manifestations is a valuable lesson. They are more apt to be overlooked. My experience with pernicious anemia is not large enough for statistical discussion. I feel that pellagra replaces pernicious anemia in the section of the country where I live. It is perhaps roughly analogous as a deficiency manifestation. In addition to giving liver by mouth in pernicious anemia, I would advise a liberal supply of vitamin B₂ such as is furnished in pellagra at the beginning of the neurologic manifestations or before they are seen.

DR. RUSSELL L. HADEN, Cleveland: Drs. Jones and Tocantins have presented a pessimistic view of the treatment of true hemophilia. My experience has been much the same. The best method of treating this condition would be the prevention of the propagation of individuals who can transmit the disease. I have had no experience with the use of liver and liver substitutes in the treatment of hemolytic jaundice. I do not see how such treatment can be of value in true congenital hemolytic icterus. I am convinced that this disease depends on the inheritance of a red cell of a certain shape. It is spheroidal instead of a biconcave disk. The bone marrow is very active in an attempt to keep pace with the excessive hemolysis. Other types of hemolytic jaundice occur that are most difficult to differentiate from pernicious anemia. Here I can see how liver therapy might help. I am optimistic about the prevention and treatment of the neurologic manifestations of pernicious anemia. I am convinced that the neurologic complications need never develop if the patient is cooperative and has been

fully and continuously treated. Intensive therapy will also ameliorate strikingly neurologic symptoms after they have developed. What are the criteria by which adequate treatment in pernicious anemia is determined? I am sure that a patient with a red cell count of only four million has not been adequately treated. With intensive therapy the erythrocyte count should be well above normal. The volume of the cell is certainly the best index of the result of treatment. So long as macrocytosis of the red cells persists, the treatment is not adequate and the deficiency responsible for the disease is not fully met. I have yet to see a patient develop a neurologic lesion if the adequacy of treatment is judged on such a basis. I should like to emphasize what Dr. Sydenstricker has said about vitamin B. There is much to suggest that the neurologic manifestations are related to a vitamin deficiency. I have given my patients large amounts of vitamin B as well as intensive liver therapy. The results of such therapy justify optimism.

DR. JACKSON BLAIR, Cleveland: Drs. Goldhamer, Bethell, Isaacs and Sturgis demonstrated that hog stomach contained an antianemic factor in large amount, and Ungley in 1931 showed that a brain tissue diet produced a reduction of anemia in pernicious anemia, being about 40 per cent equal to liver. Castle demonstrated the value of an extrinsic factor and the lack of a specific intrinsic factor in the stomach of pernicious anemia. He believes that these are important factors in the mechanism of the anemia. But the condition of the stomach in pernicious anemia is not the underlying basis of anemia any more than the condition of the pancreas in diabetes is the primary cause of diabetes. It is the straw that broke the camel's back, the final blow, responsible for the final full-blown picture. It is my opinion that the underlying basis of pernicious anemia is chronic pyelitis in its broadest meaning, and that the chronic loss of granular leukocytes from the body constitutes the reason for the chronic demand for the x-factor lacking in the developed case of pernicious anemia. I believe that Dr. Murphy's recent demonstration of the effect of liver extract on agranulocytopenia gives important additional support to this opinion. In 1930 I presented the theory that the achlorhydria is the end result of a chronic and repeated mild stimulation of gastric secretion associated with a mild chronic infection, myelitis, producing an exhaustion of the secreting mechanism of the stomach from excessive overuse, coupled with an exhaustion from the stomach tissues themselves of an anti-anemic factor, and responsible for the gastric disorder. If this theory is logical, and if the central nervous system contains a considerable amount of an antianemic factor, then similarly a chronic demand for this substance should exhaust it from these tissues. It follows that the central nervous system lesion represents an injury or scar, and the probability of cure is in rather direct ratio to the probability of cure of the stomach disorder and not directly corresponding to improvement in the blood picture. I agree with Dr. Haden in the treatment he recommends for the neurologic changes. Everything should be done to improve the blood picture. It is essential that the vitamin B complex be also given.

DR. M. A. BLANKENHORN, Cleveland: In discussing the matter with the chairman of the section, I showed him the results of treatment of neurologic complications of pernicious anemia in the medical clinic at Lakeside Hospital. We are of the opinion there, too, that if there is a degeneration of the spinal cord, as shown by objective symptoms, this degeneration cannot be improved. But we are of the opinion that many of the so-called cord symptoms are produced by peripheral neuritis causing acroparesthesia and weakness. These symptoms do recover entirely. Lateral sclerosis with spasticity must be due to a definite cord change. Such spasticity does not disappear, but the patients learn to overcome it. Our form of treatment is physical therapy to overcome spasticity. I am more optimistic about improvement than Dr. Goldhamer and his collaborators are. Improvement comes by reeducation of muscles in overcoming the spasticity. I also think that these authors have not granted a sufficient period to testing the vitamin deficiency theory for the neurologic complications when they say that injections of the vitamin B complex have not cured the disease. Contemplating other deficiency diseases, one would hardly expect that it would. I should like to ask Drs.

Goldhamer, Bethell, Isaacs and Sturgis whether their patients who have continued to do badly, regardless of high blood values, have had the type of diet which Dr. Haden describes as excess of vitamin B complex, and how long they have taken it.

DR. LEANDRO M. TOCANTINS, Philadelphia: Dr. Jones and I agree with Dr. Sachs that the hygienic measures are helpful but we doubt that they have any specific effect at all or any permanent effect whatever. We have used theelin, with negative results, during the acute phase of the disease. This point has been gone over by Albright and Brown, who observed no significant changes in the coagulation of the blood after giving enormous amounts of theelin to a hemophilic patient. It seems that most of the disagreement in the literature concerning the effects of various measures is due first to the conception that measures that tend to accelerate the clotting time of normal blood will also accelerate clotting in the hemophilic patient, who has a clotting system all his own. Many measures for accelerating the clotting of normal blood do not affect the hemophilic blood. The reverse is also true. For instance, if a citrated blood transfusion is given to a patient with hemophilia it will shorten his coagulation time. If a citrated blood transfusion is given to a normal individual in adequate amounts, it will generally prolong the coagulation time slightly. The reverse is noticed when tissue fibrinogen is given; it leads to hypercoagulability of normal blood. If given to a patient with hemophilia it does not alter the coagulation. The other concept is that control of coagulation necessarily means control of the bleeding. There are many diseases accompanied by slight or no changes in the coagulation time that show severe bleeding manifestations. One need only look at the thrombopenias with an increased bleeding time, and normal or only slightly delayed clotting time. Blood transfusion affects the skin bleeding time and does not alter the blood clotting time but leads to the cessation of bleeding. These and other facts lead to our belief that hemostasis is not synonymous with control of coagulation of the blood. It depends on extrahemic as well as on hemic factors. This has come to be more and more appreciated with advance in the investigation of diseases of the peripheral vessels by more delicate technical methods.

DR. S. M. GOLDHAMER, Ann Arbor, Mich.: My associates and I had anticipated the objection to the choice of four million red cells per cubic millimeter as being the lower limit of normal and therefore expressed it as an "arbitrary" selection. We are not of the opinion that this is a highly desired level. On the other hand, in the routine examination of patients at the Simpson Memorial Institute, less than 10 per cent of the normal patients ever have a red blood cell count as high as five million cells per cubic millimeter but usually fall in the range between four and five million cells. We have given vitamins to many of our patients with combined degeneration, with no apparent differences in response to those who received vitamins and those that did not. Treatment with vitamins is not the answer to the problem, for multiple types of therapy are being tried, in the absence of specific medication. As for the kidney being the seat of the difficulty in pernicious anemia, it appears that if this were true the proper type of treatment would be feeding kidney. Furthermore, only 40 per cent of the patients with pernicious anemia had kidney disorder and in those patients in whom the genito-urinary infection "cleared up" the disease pernicious anemia has persisted. If the psychoses present are directly related to pernicious anemia, improvement can be expected when adequate therapy is instituted; however, we have seen cases in which, for instance, schizophrenia is present in addition to pernicious anemia; naturally there is no improvement in this type.

DR. ELLERGY G. ALLEN, Syracuse, N. Y.: Dr. Reifenstein and I agree with Dr. Sachs that relapses may occur in hemolytic jaundice without treatment. However, there is possibly some significance in the fact that in one case, treated continuously with liver extract over a period of four years, there was no occurrence of a hemolytic crisis. In the two other cases, treated over periods of ten months and six months respectively, no hemolytic crisis occurred. The treatment we concentrated, 3 cc. a week. In answer to Dr. Sydenstricker's question about the change in the antibody level, I will

8. The trial of defibrinated blood injected intravenously is indicated.

9. Endocrinotherapy, according to our criteria, has been of no value.

10. Any therapeutic measure that diminishes venous clotting time and does not lessen the bleeding phenomena, or even increases them, should be avoided.

11. The use of special diets has proved disappointing.

12. Intradermal injections of antihuman platelet serum was followed sometimes by a marked decrease of the venous clotting time in three hemophilic patients, two of whom were going through an acute phase of bleeding; no prompt and permanent cessation of the bleeding followed the injections.

13. In an acute emergency due to hemorrhage, intraperitoneal transfusion is not indicated. Blood must be injected into a vein.

If the psychoses present are directly related to pernicious anemia, improvement can be expected when adequate therapy is instituted; however, we have seen cases in which, for instance, schizophrenia is present in addition to pernicious anemia; naturally there is no improvement in this type.

DR. ELLERGY G. ALLEN, Syracuse, N. Y.: Dr. Reifenstein and I agree with Dr. Sachs that remissions may occur in hemolytic jaundice without treatment. However, there is possibly some significance in the fact that in one case, treated continuously with liver extract over a period of four years, there was no occurrence of a hemolytic crisis. In the two other cases, treated over periods of ten months and six months respectively, no hemolytic crisis occurred. The treatment we are now giving our patients is intramuscular liver extract, concentr 3 week. In answer to Dr. Sydenstricker's questi e in the reticulocyte level, I might

right side, and bled easily. There was no thickening of the broad ligaments. Squamous cell carcinoma was revealed by biopsy, and radium and roentgen radiation therapy was administered.⁵

For a year and a half after the radiation therapy, follow-up examinations had shown no evidence of disease and the patient had been in excellent health. Then she began to have severe pains in the bladder, associated with some blood in the urine. These symptoms persisted for three weeks. When the patient returned to the clinic, cystoscopic examination revealed several submucous hemorrhages on the posterior wall of the bladder, in the center of which was a white, irregular area about 2.5 cm. in diameter. Subsequent examinations showed a definite ulcer in the irregular area mentioned. One year following the initial cystoscopic examination, the ulcer had disappeared completely except for a small area of submucous hemorrhage due to separation of the slough a few days previously.

Approximately a year and nine months subsequent to treatment the patient began to have unusual abdominal symptoms, simulating intestinal obstruction. Roentgen examination of the colon showed no obstruction at the time of the onset of these symptoms. No further roentgen studies were made. The initial attack soon subsided, but two months later there was a recurrent attack that was more severe, and an operation was performed. There was an old inflammatory process in the uterine tubes but no evidence of carcinoma could be found. About 25 cm. proximal to the rectum there was a definite, almost complete obstruction of the sigmoid colon. It was not adherent to the pelvis. It seemed as if there were a cicatricial band in the bowel wall, with very little inflammatory reaction outside. Resection was considered, but it was deemed more advisable to make an anastomosis around the obstruction, particularly in view of the fact that the sigmoid colon was unusually long. A side-to-side anastomosis was made. The last follow-up letter from the patient, five years after operation, states that she is in normal health.

CASE 3.—A woman, aged 41, had an enlarged cervix uteri, which was bleeding and ulcerated. The principal involvement was inside the cervix, extending into the uterus and outward through the cervix, lateral to the external os. The biopsy showed squamous cell carcinoma. Radium and roentgen therapy was administered.⁶

The frequent transitory rectal sequelae immediately following these treatments were prolonged in this case. For six months the patient complained of loose stools containing unusual quantities of mucus. It is significant to note here that there was no lesion in the rectum opposite the treated area where one would presume the maximum effect of radium would prevail. The following months there was marked constipation, and, after a period of eleven days without a stool, the patient suffered from considerable abdominal distention and was readmitted to the hospital with a diagnosis of intestinal obstruction. Follow-up examinations had shown no evidence of recurrence of the malignant growth in the cervix or adnexa. Proctoscopic examinations had shown no evidence of disease. Laparotomy was not performed at this time because her symptoms were relieved by the use of enemas and hot fomentations to the abdomen.

She was subsequently readmitted to the hospital at intervals of two and six months. An attempted barium enema was expelled as soon as it had reached the sigmoid colon, apparently indicating obstruction at this level.

Fifteen months after radiation therapy a cecostomy was done and a large tube was inserted for irrigations. Later a colon roentgen examination, during which the barium suspension was injected through the colostomy tube, revealed a definite obstructing lesion in the sigmoid colon. At the subsequent operation, performed recently, the lesion proved to be a benign stricture causing complete obstruction. This portion of the

colon was resected and an end-to-end anastomosis was made. The patient's recovery following operation was uneventful and the cecostomy closed itself.

CASE 4.—A woman, aged 50, had a diffuse carcinoma of the cervix uteri involving chiefly the cervical canal (stage 1). Squamous cell carcinoma was revealed by biopsy and the patient received irradiation.⁷

Subsequent examinations revealed satisfactory progress, and the patient was in good health except for an attack of gallstone colic. Approximately three years following irradiation therapy she stated (for the first time) that she had had some blood in the stools off and on during the previous year which she attributed to hemorrhoids. Unusual constipation was also present. Pelvic and proctoscopic examinations showed nothing except the hemorrhoids, and these were treated by the injection method. A colon roentgen examination, however, revealed an annular filling defect in the sigmoid colon, and reexamination one month later revealed the same finding. Bleeding continued at intervals and in one instance there was a cupful of blood clots.

At operation (three and one-half years following radiation therapy) the lesion proved to be a benign stricture. This portion of the colon was resected and an end-to-end anastomosis was made. Death from local peritonitis followed fifteen days after the operation.

CASE 5.—A woman, aged 59, suffered from a rather extensive carcinoma of the cervix uteri, involving chiefly the anterior lip of the cervix and extending into the vaginal wall. The lesion, as determined by biopsy, was a squamous cell carcinoma. The patient was treated with radium⁸ but received no roentgen therapy.

The patient made satisfactory progress but complained of slight constipation, which was unusual for her. Seven months following radium irradiation she stated that during the past few weeks the constipation had become more severe and that she had passed darkened blood, blood clots, and mucus by rectum, associated with cramplike abdominal pains. Pelvic examination showed nothing of significance, but roentgen examination of the colon revealed a conical, fixed, concentric narrowing in the midsigmoid area, believed to be due to an irradiation stricture. At operation the stricture was immediately behind the fundus of the uterus. This area appeared anemic as compared with the remainder of the sigmoid colon. A cecostomy was performed and one month later a resection of the lesion and an end-to-end anastomosis were done. The patient was discharged from the hospital one month after operation having normal stools.

CASE 6.—A woman, aged 58, had a carcinoma of the cervix uteri, involving chiefly the posterior lip and the posterior vaginal wall. The pathologic diagnosis was squamous cell carcinoma. Radium therapy was followed by roentgen irradiation.⁹

For five months the patient showed satisfactory progress with complete regression of the lesion but did not return for the usual subsequent examinations. Two months later, in a letter from the patient's husband, who was a physician in a distant town, it was learned that the patient had been confined to bed for a month because of abdominal pain, nausea and pronounced vomiting. He stated that examination revealed no evidence of carcinoma in the cervix or in neighboring structures. Death followed one month later. Autopsy was performed, which revealed an inflammatory stricture of the small intestine, causing a definite obstruction. The exact relation of this area to the uterus was not stated, but examination of this area of the intestine and the uterus, after removal from the abdomen, revealed adhesions on the peritoneal surfaces of both.

7. Two tubes containing 244 millicuries of radon were inserted, one in the cervix and one against the cervix, for ten hours, or a total of approximately 2,440 millicurie hours. One month later, roentgen therapy was administered.

5. Two tubes containing 305 millicuries of radon were inserted into the uterus and cervix and two tubes containing 140 millicuries of radon were placed against the cervix for six and a half hours, producing a total irradiation of about 2,759 millicurie hours. Twelve days later, roentgen therapy was started.

6. One tube containing 106 millicuries of radon was placed in the fundus of the uterus, one tube containing 247 millicuries of radon was placed in the cervix, and four tubes containing 142 millicuries were placed against the cervix for eight hours, or a total of approximately 3,960 millicurie hours. One month later roentgen therapy was administered.

8. One tube containing 266 millicuries of radon was inserted into the cervical canal, and ten radium needles, each containing 10 mg. of radium, were inserted into the carcinomatous mass, approximately 1 cm. apart, and one tube containing 107 millicuries of radon was placed against the anterior lip of the cervix, a total of 373 millicuries of radon and 100 mg. of radium for seven and one-half hours, equivalent to approximately 3,729 mg. hours of radium.

9. One tube containing 118 millicuries of radon was placed in the cervix and another tube containing 177 millicuries of radon was placed against the posterior lip of the cervix, for ten hours, or a total of approximately 2,950 millicurie hours. One and a half months later, roentgen therapy was administered.

say that in case 1 the reticulocytes fell from 10 to 4 per cent as the anemia improved. As to the action of liver extract or how it may affect the blood picture in hemolytic jaundice, we are unprepared to say. In answer to Dr. Haden's question about the type of case treated, I think it is fairly certain that the first case presented was, without doubt, a congenital case. It will be recalled that the family history was positive. The father has had recurrent attacks of jaundice for many years. He now has an increased icterus index and his blood cells show increased tendency to hemolysis as estimated by the hypotonic saline solutions. This boy definitely improved when treated with liver extract, whereas prior to treatment he had had a hemolytic crisis occurring every two or three months. Since he has had treatment continuously, he has had no hemolytic crisis and his blood count is improved very much.

RESULTS OF PROLONGED IRRADIATION FOR MALIGNANT CONDITIONS OF PELVIS

INTESTINAL, RECTAL AND BLADDER COMPLICATIONS;
SURGICAL TREATMENT

THOMAS E. JONES, M.D.
CLEVELAND

In a previous communication¹ I directed attention to early and late effects of radiation in the rectum and bladder following radium and roentgen irradiation for carcinoma of the cervix. Attention was directed to the importance of differentiating between late reactions and recurring malignant lesions, because further irradiation of the benign condition may cause further insult to the tissue and result in irreparable damage, such as fistulas in the bladder or rectum.

The present study directs attention to a rather new clinical entity² that may develop and call for surgical intervention many months or years after complete regression or cure of the cervical cancer. In a series of 520 patients with cervical carcinomas having received radiation therapy at the Cleveland Clinic, there have been seven known cases of benign stricture of the intestine causing obstruction that might easily have been construed as, or confused with, metastatic carcinoma. In five of these cases the obstruction was in a movable segment of the sigmoid and in two cases in the small intestine. All these strictures were observed in patients who had been irradiated for carcinoma of the cervix, but the increasing use of radiation for other conditions necessitating exposure of the intestine may result in similar complications. Subsequent to the radiation therapy no evidence of carcinoma was found in these cases and, judging by present-day standards, none of these patients received excessive irradiation. Since similar methods of therapy are in general use, it seems probable that the incidence of the lesion is greater than is surmised at the present time; and if similar cases have been attributed to metastasis in the past, the mortality statistics relating to metastasis from cervical carcinoma are open to question. Desjardins,³ in a report of the literature, has called attention to intestinal injury produced experimentally by irradiation.

From the Cleveland Clinic.

Read before the Section on Surgery, General and Abdominal, at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 14, 1934.

2. Collins, E. N., and Jones, T. E.: *Benign Stricture of the Intestine Due to Irradiation of Carcinoma of the Cervix Uteri*, Surg., Gynec. & Obst. 59: 644-649 (Oct.) 1934.

3. Desjardins, A. U.: *Action of Roentgen Rays and Radium on Gastro-Intestinal Tract: Experimental Data and Clinical Radiotherapy*, Am. J. Roentgenol. 26: 145 (July), 335 (Aug.), 493 (Sept.) 1931.

There are many reports in the literature dealing with the manifestations of acute injury to the intestine following irradiation, both experimental and clinical, but I have not been able to trace any reports on patients who have recovered from the acute symptoms and have later developed the chronic condition herein described. If such cases have been described, this report adds seven cases of intestinal obstruction that developed in patients from eight months to eight years after radiation therapy for cervical carcinoma.

The rate of recurrence of cancer is so high that almost any abdominal or pelvic pain may quite naturally and logically be attributed to malignant extension or metastasis. If the condition actually is a benign stricture caused by irradiation, it is quite obvious that additional x-ray treatment would only aggravate the condition and hasten the end. Therefore, one should always keep in mind the possibility that a patient who exhibits unusual abdominal symptoms, particularly if they simulate intestinal obstruction, several months or even years following radiation therapy, may have a stricture of the intestine and may be restored to normal health by resection of the lesion. Before this disability is attributed to metastasis, thorough reexamination by sigmoidoscopic and roentgenographic studies should be made to eliminate the possibility of this curable complication. While roentgen examinations demonstrate lesions in the sigmoid quite readily, strictures in the small intestine are quite difficult to visualize unless the obstruction is practically complete. In this type of case it is inadvisable to give barium in any large amounts, and therefore exploratory operation is warranted, especially in patients in whom there is no evidence of recurring carcinoma in the pelvis.

REPORT OF CASES

A brief review of the case histories will serve to clarify the problems involved:

CASE 1.—A woman, aged 60, when first examined had a carcinoma of the cervix uteri, extending into the broad ligament. Biopsy taken at the time of treatment showed a squamous cell carcinoma, and the patient was treated with radium and roentgen rays in 1927.⁴

Follow-up examinations had shown no evidence of malignant disease, and the patient had been in excellent health for more than two years after the last radium treatment. Then in 1929 unusual constipation set in, which became progressively more severe and at the time of readmission, a few weeks after its onset, she had symptoms and signs of intestinal obstruction. Proctoscopic examination yielded no information, and no blood or mucus was seen in the bowel. Roentgen examination of the colon revealed an obstructing lesion in the sigmoid colon, which was believed to be due to carcinoma. At operation, the lesion had the characteristics of a benign stricture. It was a napkin ring deformity, with a few firm adhesions to the omentum. The adhesions were severed, this portion of the colon was resected, and an end-to-end anastomosis was made. The pathologic diagnosis was chronic inflammation. The patient recovered well from the operation and has reported normal health on numerous occasions during the four and one-half years since the resection was performed.

CASE 2.—A woman, aged 52, had had a pelvic abscess years previously and came to the clinic because of pelvic pain. The cervix uteri was firm, enlarged and nodular, especially on the

4. One tube containing 170 millicuries of radon was inserted into the cavity of the uterus and cervical canal for twelve hours, producing a total irradiation of 2,040 millicurie hours. Three days later, roentgen therapy was started. Two months later a second radium treatment was administered to the cervix, 220 millicuries of radon being used in four tubes against the cervix for ten hours, totaling 2,200 millicurie hours, a total of approximately 4,240 millicurie hours for the two radium treatments. The actual amount of radiation received represents about 3 per cent less than these figures when calculated according to the time the radon is in place.

right side, and bled easily. There was no thickening of the broad ligaments. Squamous cell carcinoma was revealed by biopsy, and radium and roentgen radiation therapy was administered.⁵

For a year and a half after the radiation therapy, follow-up examinations had shown no evidence of disease and the patient had been in excellent health. Then she began to have severe pains in the bladder, associated with some blood in the urine. These symptoms persisted for three weeks. When the patient returned to the clinic, cystoscopic examination revealed several submucous hemorrhages on the posterior wall of the bladder, in the center of which was a white, irregular area about 2.5 cm. in diameter. Subsequent examinations showed a definite ulcer in the irregular area mentioned. One year following the initial cystoscopic examination, the ulcer had disappeared completely except for a small area of submucous hemorrhage due to separation of the slough a few days previously.

Approximately a year and nine months subsequent to treatment the patient began to have unusual abdominal symptoms, simulating intestinal obstruction. Roentgen examination of the colon showed no obstruction at the time of the onset of these symptoms. No further roentgen studies were made. The initial attack soon subsided, but two months later there was a recurrent attack that was more severe, and an operation was performed. There was an old inflammatory process in the uterine tubes but no evidence of carcinoma could be found. About 25 cm. proximal to the rectum there was a definite, almost complete obstruction of the sigmoid colon. It was not adherent to the pelvis. It seemed as if there were a cicatricial band in the bowel wall, with very little inflammatory reaction outside. Resection was considered, but it was deemed more advisable to make an anastomosis around the obstruction, particularly in view of the fact that the sigmoid colon was unusually long. A side-to-side anastomosis was made. The last follow-up letter from the patient, five years after operation, states that she is in normal health.

CASE 3.—A woman, aged 41, had an enlarged cervix uteri, which was bleeding and ulcerated. The principal involvement was inside the cervix, extending into the uterus and outward through the cervix, lateral to the external os. The biopsy showed squamous cell carcinoma. Radium and roentgen therapy was administered.⁶

The frequent transitory rectal sequelae immediately following these treatments were prolonged in this case. For six months the patient complained of loose stools containing unusual quantities of mucus. It is significant to note here that there was no lesion in the rectum opposite the treated area where one would presume the maximum effect of radium would prevail. The following months there was marked constipation, and, after a period of eleven days without a stool, the patient suffered from considerable abdominal distention and was readmitted to the hospital with a diagnosis of intestinal obstruction. Follow-up examinations had shown no evidence of recurrence of the malignant growth in the cervix or adnexa. Proctoscopic examinations had shown no evidence of disease. Laparotomy was not performed at this time because her symptoms were relieved by the use of enemas and hot fomentations to the abdomen.

She was subsequently readmitted to the hospital at intervals of two and six months. An attempted barium enema was expelled as soon as it had reached the sigmoid colon, apparently indicating obstruction at this level.

Fifteen months after radiation therapy a cecostomy was done and a large tube was inserted for irrigations. Later a colon roentgen examination, during which the barium suspension was injected through the colostomy tube, revealed a definite obstructing lesion in the sigmoid colon. At the subsequent operation, performed recently, the lesion proved to be a benign stricture causing complete obstruction. This portion of the

colon was resected and an end-to-end anastomosis was made. The patient's recovery following operation was uneventful and the cecostomy closed itself.

CASE 4.—A woman, aged 50, had a diffuse carcinoma of the cervix uteri involving chiefly the cervical canal (stage 1). Squamous cell carcinoma was revealed by biopsy and the patient received irradiation.⁷

Subsequent examinations revealed satisfactory progress, and the patient was in good health except for an attack of gallstone colic. Approximately three years following irradiation therapy she stated (for the first time) that she had had some blood in the stools off and on during the previous year which she attributed to hemorrhoids. Unusual constipation was also present. Pelvic and proctoscopic examinations showed nothing except the hemorrhoids, and these were treated by the injection method. A colon roentgen examination, however, revealed an annular filling defect in the sigmoid colon, and reexamination one month later revealed the same finding. Bleeding continued at intervals and in one instance there was a cupful of blood clots.

At operation (three and one-half years following radiation therapy) the lesion proved to be a benign stricture. This portion of the colon was resected and an end-to-end anastomosis was made. Death from local peritonitis followed fifteen days after the operation.

CASE 5.—A woman, aged 59, suffered from a rather extensive carcinoma of the cervix uteri, involving chiefly the anterior lip of the cervix and extending into the vaginal wall. The lesion, as determined by biopsy, was a squamous cell carcinoma. The patient was treated with radium⁸ but received no roentgen therapy.

The patient made satisfactory progress but complained of slight constipation, which was unusual for her. Seven months following radium irradiation she stated that during the past few weeks the constipation had become more severe and that she had passed darkened blood, blood clots, and mucus by rectum, associated with cramplike abdominal pains. Pelvic examination showed nothing of significance, but roentgen examination of the colon revealed a conical, fixed, concentric narrowing in the midsigmoid area, believed to be due to an irradiation stricture. At operation the stricture was immediately behind the fundus of the uterus. This area appeared anemic as compared with the remainder of the sigmoid colon. A cecostomy was performed and one month later a resection of the lesion and an end-to-end anastomosis were done. The patient was discharged from the hospital one month after operation having normal stools.

CASE 6.—A woman, aged 58, had a carcinoma of the cervix uteri, involving chiefly the posterior lip and the posterior vaginal wall. The pathologic diagnosis was squamous cell carcinoma. Radium therapy was followed by roentgen irradiation.⁹

For five months the patient showed satisfactory progress with complete regression of the lesion but did not return for the usual subsequent examinations. Two months later, in a letter from the patient's husband, who was a physician in a distant town, it was learned that the patient had been confined to bed for a month because of abdominal pain, nausea and pronounced vomiting. He stated that examination revealed no evidence of carcinoma in the cervix or in neighboring structures. Death followed one month later. Autopsy was performed, which revealed an inflammatory stricture of the small intestine, causing a definite obstruction. The exact relation of this area to the uterus was not stated, but examination of this area of the intestine and the uterus, after removal from the abdomen, revealed adhesions on the peritoneal surfaces of both.

7. Two tubes containing 244 millicuries of radon were inserted, one in the cervix and one against the cervix, for ten hours, or a total of approximately 2,440 millicurie hours. One month later, roentgen therapy was administered.

8. One tube containing 266 millicuries of radon was inserted into the cervical canal, and ten radium needles, each containing 10 mg. of radium, were inserted into the carcinomatous mass, approximately 1 cm. apart, and one tube containing 107 millicuries of radon was placed against the anterior lip of the cervix, a total of 373 millicuries of radon and 100 mg. of radium for seven and one-half hours, equivalent to approximately 3,729 mg. hours of radium.

9. One tube containing 118 millicuries of radon was placed in the cervix and another tube containing 177 millicuries of radon was placed against the posterior lip of the cervix, for ten hours, or a total of approximately 2,950 millicurie hours. One and a half months later, roentgen therapy was administered.

5. Two tubes containing 305 millicuries of radon were inserted into the uterus and cervix and two tubes containing 140 millicuries of radon were placed against the cervix for six and a half hours, producing a total irradiation of about 2,759 millicurie hours. Twelve days later, roentgen therapy was started.

6. One tube containing 106 millicuries of radon was placed in the fundus of the uterus, one tube containing 247 millicuries of radon was placed in the cervix, and four tubes containing 142 millicuries were placed against the cervix for eight hours, or a total of approximately 3,960 millicurie hours. One month later roentgen therapy was administered.

From these observations it may be inferred that the stricture of the small intestine involved an area adjoining the uterus, that fibrous adhesions formed between the two, and that the cause of death (since no other cause was considered or found) was severe toxemia, resulting from obstruction of the small intestine.

CASE 7.—A woman, aged 42, admitted to the clinic, June 1, 1926, had had vaginal bleeding for one year. Examination showed extensive papillary carcinoma of the cervix with involvement of the vaginal wall anteriorly and posteriorly, but apparently there was no invasion of the broad ligament. Radium and roentgen irradiation were administered in June 1926.¹⁰

About six months later the patient reported that for a month she had been having trouble with the rectum. The symptoms included tenesmus, mucus, and blood in the stools. This gradually subsided and when the patient was examined a year after treatment there was a narrowing of the rectum opposite the cervix, but the lumen easily admitted the index finger. The patient had no abdominal complaints.

In October 1930, more than four years after irradiation, the patient complained of recurring attacks of abdominal pain which her physician attributed to gallbladder disease. Roentgenographic examination of the gastro-intestinal tract at that time showed no abnormality except a nonfunctioning gallbladder. The attacks of pain continued at occasional intervals until March 1934, when she suffered a very severe one, at which time she had been ill with abdominal pain, nausea and vomiting for two weeks and had lost a great deal of weight. She reentered the Clinic Hospital, April 7, 1934, nearly eight years after the course of radiation therapy. While at the time of hospitalization there was no evidence of obstruction, it was felt that the last attacks simulated an obstruction, and operation was advised.

Exploratory laparotomy was performed, April 10. In the small intestine, 3 feet from the ileocecal valve there was an almost complete obstruction, with collapse below and considerable dilation above the stricture. About 4 inches above this there was a slight narrowing of the lumen. A resection of about 8 inches of small intestine and an end-to-end anastomosis were done. The patient made an uneventful convalescence and was out of the hospital on the fourteenth day. On the fifteenth postoperative day she experienced a sudden severe pain in the right lower quadrant with some abdominal distention, but there was no elevation in temperature or increased pulse rate. The patient was treated expectantly for five days apparently satisfactorily, when distention recurred and exploration was done. There was some free fluid in the abdomen and some distended coils of intestine, one of which was used for ileostomy. We were dealing with a mesenteric thrombosis. The ileostomy functioned quite satisfactorily but the patient gradually failed and died, about two weeks later, on May 13.

The pathologic report on the lesion removed was as follows: A longitudinal section of the small intestine showed marked thickening and dense fibrosis of the serosal coat in which there were large numbers of greatly thickened arteries, showing varying degrees of obliterative endarteritis, degeneration of the lamina elastica and hyalinization of the intima, with no calcification present. In some areas there was localized, perivascular, inflammatory infiltration, with plasma cells predominating. There was considerable diffuse increase of fibrous tissue in the muscular coat, with fibrosis of the submucosa. The mucosa was somewhat atrophic, contained very little lymphoid tissue and showed mild, diffuse, inflammatory infiltration, with numerous eosinophils and plasma cells present. In one area there was active ulceration, with almost complete destruction of mucosa. The base of the ulcer extended into the muscular coat. There was some fibrinous exudate, in which were many leukocytes together with plasma cells, eosinophils and lymphocytes. Ganglion cells of the submucosa showed extensive degenerative changes in the neighborhood of the ulcer. There was no evidence of neoplasm.

10. The first application of radium consisted of 3,584 mg. hours with tubes and needles in and against the cervix, and roentgen irradiation was given about three weeks later. A second application of radium to the cervix, amounting to 1,300 mg. hours, was administered about a month after the roentgen therapy.

In this case the small intestine, which was only .8 feet (244 cm.) long, accounted for the fact that the patient was losing weight in spite of a good appetite for years. The absorptive mucosa was destroyed and replaced by fibrous tissue.

COMMENT

This group of cases is of particular interest to me because I administered the radium in all cases and have had the surgical management of the resulting complications. The x-ray therapy was administered by Dr. Portmann. Obviously, as is the case in any pathologic process, the factor of particular interest is the causation and possible prevention of the lesion. In this case the radium therapist is likely to blame the x-ray therapist and vice versa, whereas both probably have contributed to the causation of the lesion. It is significant to note that in this series only one patient had any lesion in the rectum opposite the cervix where the maximum intensity of radium radiation would be delivered. With the obstruction of the small intestine in case 7 there was a slight narrowing of the rectum that was readily dilatable. This would seem to justify the statement that the radium dosage used in this series was not excessive.

That roentgen irradiation is not entirely responsible is a justifiable assumption because patient 5 received no x-ray therapy. Furthermore, the lesion in this case was not at the point of maximum intensity but in the sigmoid several inches away. One then must search for causes that contribute to fixation of a certain loop of small or large intestine in the pelvis which is the recipient of the maximum radium and roentgen dosage at that particular point. Previous inflammatory disease of the pelvic organs, either specific or post partum, might tend to fix a loop at a vulnerable point, yet this was not a factor in this group of cases, because in only one was the bowel fixed in the bottom of the pelvis by an apparent previous inflammatory process.

From my observations I would venture the following explanation, which may apply in the majority of cases: The initial insult is delivered by radium. If a loop of small or large intestine remains in the same position in the culdesac during the entire time of radium irradiation, the erythema produced at this point may be sufficient to produce a simple local peritonitis, which would fix the bowel at this point temporarily, and before the exudate is completely absorbed roentgen rays are administered, thus furnishing additional irritation, which is sufficient to cause an ulceration in the mucosa that eventually goes on to stricture formation. As time passes the exudate is absorbed and the bowel becomes free, which is the general finding at operation.

Whether this intestinal lesion is due to one agent or the other or to a combination of the two, ways and means should be devised to prevent it. A change of position of the patient during treatment suggests itself as an aid, but this would not be entirely safe for fear of dislodging the radium tubes and possibly causing damage to the rectum or bladder. However, a Trendelenburg position maintained during treatment may help to keep the intestine out of the pelvis while the latter is being irradiated both by radium and by x-rays. If the theory of some fixation of a loop of intestine is tenable, drugs to stimulate peristalsis may be considered, and it might be advisable to give from 0.5 to 1 cc. of ampoules of pitressin every four hours while the radium is in place or just previous to an x-ray treatment in order to keep the intestine moving and thus to preclude excessive irradiation of any one loop.

In presenting these intestinal complications I do not wish to convey the idea that I disparage the present-day treatment of cancer of the cervix. I believe it is the best that is offered and shall continue to use it. However, on the basis of the experience here reported, I would interject a word of caution regarding the step that is being taken at the present time, the stepping up of the voltage many times more than is in use now, because I think increased voltages carry a definite potential danger of damage to the intestine.

CONCLUSIONS

The recognition of the possibility of benign stricture of the intestine as a complication following radiation therapy, often months or years later, is of utmost importance, for it can very easily be confused with recurrence of a malignant condition. Its detection and surgical treatment may salvage the lives of many patients otherwise regarded as having a hopeless malignant growth.

ABSTRACT OF DISCUSSION

DR. GEORGE GRAY WARD, New York: In a series of 655 cases of cancer of the cervix under my care at the Woman's Hospital, I have observed fourteen cases in which intestinal complications exclusive of the rectum developed. Thirteen of these presented symptoms of partial or complete obstruction, and one involvement of the sigmoid without obstruction. Some were associated with fecal fistulas. In eight of these cases the diagnosis was confirmed by operation or autopsy, and in seven of them metastatic carcinoma of the intestine was found as well as adhesions and inflammatory exudate. Proctitis as evidenced by diarrhea, rectal pain and ulcerations has occurred in about 3 per cent of the cases. There were twenty-two rectovaginal fistulas with three spontaneous and two operative closures, and twenty-one vesicovaginal fistulas with no spontaneous and two operative closures. Eighty-eight per cent of these fistula cases were classed in groups III and IV on their first visit, and five had developed the complication previous to the irradiation. I therefore believe that the extent of the cancer was the causative factor in the majority of these cases rather than the irradiation. Carcinoma of the cervix stump following a supravaginal hysterectomy occurred in forty-seven of 655 cases, or about 7 per cent. In these cases the incidence of fistula was about twice the incidence in old cases. I believe that irradiation under these conditions is much more dangerous, as the bladder lies on top of the cervix at the site of the amputation, where it will come in close contact with the radium tube placed in the cervical canal. Consequently in these cases I have reduced the initial dosage about one half and repeat as necessary. I have encountered ureter and kidney complications from obstruction in eighteen cases as a late result. In many cases I believe it due to contraction of postirradiation connective tissue formation in the broad ligaments, and it is now my practice to pass ureteral catheters as a diagnostic measure in all late cases in which pelvic symptoms develop. Severe deep seated pelvic pain and edema of the extremities may be due to the same cause and not necessarily to metastatic cancer. While in the cases that came to operation or autopsy all but one of the intestinal complications were the result of recurrent carcinoma, nevertheless I appreciate the likelihood of benign postirradiation adhesions being a cause of trouble, as Dr. Jones has found. I am inclined to the belief that prolonged and repeated high voltage roentgen therapy is the most probable cause in the majority of cases of benign stricture of the intestine as the effective range of the radium is so limited, except in those cases in which a loop of intestine is adherent to the posterior surface of the uterus or culdesac. It will take time to determine whether the fractional method of Coutard is the safer technic. In view of Dr. Jones's experience and my own, I wish to advocate that, in all cases in which late postirradiation symptoms of intestinal or ureteral obstruction, severe pain or edema develop, an exploratory laparotomy be

done with the object of making an exact diagnosis and relieving the obstruction if due to benign adhesions, enucleation of any involved pelvic glands as suggested recently by Taussig, and a sympathectomy of the presacral nerve for the relief of pain. As many of these patients develop symptoms after the customary five year period of observation, I consider that a ten year period is necessary for the more correct evaluation of radiation therapy.

THE SIGNIFICANCE OF MIXED INFECTIONS IN PNEUMOCOCCIC PNEUMONIA

MAXWELL FINLAND, M.D.

BOSTON

It is my purpose in this communication to call attention to an important group of cases of pneumococcic pneumonia in which multiple bacterial agents are operative. The significance of these mixed infections in altering the course and outcome of the disease and in evaluating the effects of certain specific therapeutic agents will be brought out by citing a few examples.

Numerous instances of cases from which more than one strain or species of bacterium were isolated in the course of the disease may be found in the literature concerning pneumococcic pneumonia. Either most of these instances are recorded as part of intensive bacteriologic investigations of small groups of cases or they are mentioned in the reports of clinical and bacteriologic studies of large numbers of pneumonia cases.¹ In such reports little attention has been given to the significance of each of the various agents and its rôle in the individual case. Isolated examples of carefully studied cases of mixed infections in pneumonia, however, are to be found scattered among reports dealing with the evaluation of specific therapeutic agents² or where epidemiologic or immunologic studies have been undertaken simultaneously.³ Further examples are

This study was aided, in part, by a grant given in honor of Francis Weld Peabody by the Ella Sachs Plotz Foundation.

to be found in reports on epidemics of pneumonia, particularly those complicating influenza or measles.⁴

Many methods are employed to determine or to isolate the bacterial incitants in pneumonia. Ordinarily the sputum is utilized for this purpose. The organism, usually a single strain (type) of pneumococcus, is obtained by inoculating the sputum into a mouse and identified from the peritoneal exudate or heart's blood of the animal by its morphologic, cultural and serologic characteristics.⁵ When sputum cannot be obtained, suitable culture of material obtained by swabbing the throat may be utilized either directly or after mouse inoculation. Other methods involve tests for soluble and specifically reacting substances in the sputum⁶ or urine,⁷ or tests for specific serologic reactions of organisms observable directly in sputum.⁸ These methods are designed primarily for the isolation and serologic classification of pneumococci, but occasionally they yield

the infected pleural cavity in the living patient, or from these and other portions of the body at necropsy. Additional valuable information may be obtained from the reactions of the serum of the convalescent patient with type-specific organisms (agglutinins) or their products (precipitins), or by testing the capacity of such serum to protect animals against multiple lethal doses of virulent specific organisms.¹⁰

No effort will be made here to evaluate the relative importance of each of these methods. It is merely to be pointed out that the frequency with which multiple bacterial strains are encountered is directly proportional to the diversity of the methods employed. To determine the rôle that each of the agents thus identified plays in the particular disease process of any given individual necessitates the application of a combination of these methods with careful clinical and pathologic observations.

- Ty. = B. typhosus or B. paratyphosus

other organisms. For determining the presence and relative numbers of other bacteria, direct cultures on suitable mediums are employed.⁹ Organisms can also be cultured from the blood, from material obtained by direct puncture of the consolidated lung or from

SOURCE OF MATERIAL

At the Boston City Hospital, between November 1929 and May 1933, approximately 2,000 cases of pneumonia or pneumococcic infections were studied bacteriologically.¹¹ Among these were 133 cases in which pneumonia was associated with the finding of two or more organisms, at least one of which was a pneumococcus. The organisms were isolated, in almost every instance, during a period of active infection. All pneumococcus strains from these 133 patients were identified as belonging to one or another of the serologic groups I-XXXII (Cooper) with the exception of four that failed to agglutinate in antisera for types I-XX, no other serums being available at the time when they were isolated. The majority of the other organisms were isolated directly from the blood or from pleural fluid, or they were cultured at necropsy from the heart's blood, from accumulations of pus, or from the consolidated lung. Some instances are included in which the organisms were shown to be predominant in cultures made directly from the sputum or in which they were obtained from the heart's blood of a mouse

11. This work was carried out with Dr. W. D. Sutcliffe during 1929-1932 and with Dr. A. W. Winkler in the fourth year.

inoculated with sputum. Tubercle bacilli were demonstrated only in stained preparations of sputum.

The numbers of patients with the various combinations of organisms are shown in table 1. Each patient is listed only once, except in the summary columns, as indicated. A total of thirty-seven patients had more than one pneumococcus type, including four with three distinct serologic groups and four from whom other organisms were isolated in addition to the two types of pneumococci. The remaining ninety-six patients had a pneumococcus and one or more other organisms. There were, in addition, nine patients in whom immunologic reactions of serum obtained during convalescence indicated that the disease was probably caused by a pneumococcus of a different type than the one isolated from the patient. These nine cases were studied with Winkler³⁶ in 1932-1933 but they are not included in the table.

CLASSIFICATION OF CASES OF MIXED INFECTION

It is impossible to present here the details of the examinations in all the cases. A review of the data available in these cases has indicated that they may be divided roughly into three groups. In the first group are cases in which only one of the multiple bacterial agents is causing the pulmonary infection, the other probably being incidental. In the second, more than one organism is invading simultaneously, either at the same or at different sites. In the third group, one invasion follows on another and here, again, the same or different sites may be involved. A few examples of cases in each group will suffice to illustrate the significance of the various organisms in relation to the disease.

Mixed Infections, with One Organism Probably Incidental.—Examples of such cases abound in the literature. In some instances one of the organisms can be shown to be a more or less constant inhabitant of the particular individual's nasopharynx.¹² In other instances some of the bacteria may be related to the antecedent infection of the upper respiratory tract.³⁶ In the former, type III or some of the types formerly classified as group IV pneumococci are most commonly found; in the latter, influenza bacilli are by far the most frequent, particularly during epidemics. It may be noted that with the further classification of the pneumococci previously included in group IV¹³ and with the serologic identification of these organisms when associated with disease,¹⁴ it has become apparent that some of the newly classified types are regularly associated with disease processes in the lung, while others are more regularly found in normal throats and only rarely cause disease. This new classification has helped considerably in determining the relative significance of multiple bacterial invaders. In patients unable to raise sputum, or with sputum mixed with material from the nose or pharynx, or when ordinary care is not taken to obtain sputum coughed up directly from the lung, organisms not related to the disease are frequently obtained. It is such instances that account for most of the inconsistencies in sputum typings in which one of the group IV

pneumococci is obtained from one sputum and a different type obtained from another sample of the same patient's sputum or from a different source.¹⁴

CASE 1.—G. O., a man, aged 45, had coryza and generalized aches and pains, Jan. 17, 1933. The next day he had chills followed by the chest pain and respiratory distress. He was admitted to the hospital, January 20, and was found to have lobar pneumonia of the left lower lobe. His condition was very toxic and remained so until his death, January 29, the pulmonary process having extended to the upper lobe of the same lung. Sputum, obtained with difficulty in each instance, showed no pneumococci in the specimen of January 20 and type X pneumococci in those of January 21 and 27. The blood cultures made on January 20, were sterile, those on January 25 and 29 showed type I pneumococci. The patient's serum obtained January 20, 24, 25 and 29 failed to agglutinate either type I or type X. There was no autopsy.

CASE 2.—P. C., a woman, aged 26, had on Feb. 23, 1933, a sudden onset with chill, followed by fever, cough and chest pain. She entered the hospital, March 5, at which time she had lobar pneumonia of the left lower lobe. She recovered by crisis, March 7. Purulent sputum inoculated into a mouse, March 6, yielded type III pneumococci in pure culture, and on March 10 type V and no type III organisms were obtained in the same manner. Blood cultures on March 6 and 8 were both sterile. Her serum on March 6, 12, 19 and 26 showed a high titer of agglutinins and protective antibodies against type V but failed to show either antibody against type III.

The evidence in these cases appears to indicate that the type X in case 1 and the type III pneumococci in case 2 were probably not related to the pulmonary lesion.

Concurrent Infections.—Cases in which more than one type of pneumococcus have been shown to cause infection in the lung simultaneously are extremely rare. This may be due to the difficulty of isolating different types from the same culture, except by careful bacteriologic technic. Likewise, cases of lobar pneumonia with proved simultaneous infections and with pneumococci and other organisms are rare. Examples from the present series may be cited:

CASE 3.—K. P., a man, aged 43, had a mild infection of the upper respiratory tract without general symptoms, April 10, 1931. April 12, he had a severe chill followed by right-sided chest pain, fever, and cough productive of frothy red sputum. He entered the hospital, April 18, at which time he had lobar pneumonia involving the entire right lung. He was extremely ill and toxic and remained so until his death, April 24. During the last eighteen hours preceding his death he was given intravenously, 130 cc. of Felton's concentrated antibodies (types I and II) in divided doses. There was no apparent benefit from this treatment. From brown tenacious sputum, obtained April 19, both types I and III pneumococci were isolated, but only the former were recovered from a mouse inoculated with similar sputum on April 22. The blood cultures made, April 23, before serum was given, showed 126 colonies per cubic centimeter of blood, and cultures from picked colonies agglutinated in type I serum only. A second blood culture made two hours after 5 cc. of serum was given showed thirty-six colonies per cubic centimeter of blood. Another 25 cc. of serum was given and two hours later fifty-eight colonies were cultured from 1 cc. of blood. Two additional doses of 30 cc. of antibody were given. From the second and third blood cultures only type I pneumococci could be identified. A culture on the following morning showed approximately 2,700 colonies per cubic centimeter of blood, but from these colonies only type III pneumococci and

not type I could be isolated. Immediately after death, which occurred seven hours after the last blood culture was made, thoracentesis revealed no free fluid in the right pleural cavity, but from thick bloody purulent material obtained directly from the lung both type I and type III organisms were isolated.

CASE 4.—H. T., a man, aged 55, was suddenly taken ill, Feb. 14, 1930, with a chill, followed by fever and cough productive of blood tinged sputum. He entered the hospital February 16, with evidence of incipient delirium tremens and signs of lobar pneumonia of the right lower lobe. His condition grew rapidly worse and he died about thirty-six hours after admission. Type VI pneumococci and Friedländer's bacilli were obtained from thick, brown, somewhat foul-smelling sputum raised at the time of admission. Blood cultures made at the same time showed a pure culture of Friedländer's bacilli in broth, but the pour plates remained sterile. At autopsy the right lower lobe was uniformly consolidated and the cut section was gray, mucoid and stringy, and showed many areas of necrosis. The upper and middle lobes showed red hepatization. Cultures from the heart's blood and the right lower lobe showed Friedländer's bacilli only, and these organisms were demonstrated in large numbers in the microscopic sections from this lobe. From the right middle lobe, a pure culture of type VI pneumococci was grown and no Friedländer's bacilli were obtained.

Case 3 probably represents a concurrent infection, apparently of the same lobe, with types I and III pneumococci, both invading the blood stream, the latter type predominating before death, after type I antibodies had been given. This therapeutic procedure may possibly have caused the removal of the homologous type pneumococci from the circulating blood. Case 4 represents a simultaneous infection of two different portions of the lung, each with a different organism.

Consecutive Infections (Superinfections).—From the army camps during the World War there were reported a few instances of definite superinfections in cases of pneumococcic lobar pneumonia that were observed clinically and studied bacteriologically and pathologically.⁴ These observations were made during epidemics of measles or influenza. Usually hemolytic streptococci, but occasionally staphylococci or other types of pneumococci, were shown to be the causative agents in these secondary infections. In nonepidemic periods occasional cases of late infections with other organisms complicating the course of pneumococcic lobar pneumonia are mentioned by various writers, usually as incidental observations in discussing failure-of specific therapeutic agents.² Many such instances have been observed among the cases enumerated in table 1. In a number of these cases immunologic, as well as bacteriologic and postmortem, studies were made. Three cases of this sort are cited:

CASE 5.—M. L., a man, aged 43, had an infection of the upper respiratory tract, Feb. 18, 1930. He still had some residual symptoms on February 24, when he was suddenly taken with a chill followed by marked prostration, chest pain and cough productive of rusty sputum. He entered the hospital, February 26, showing signs of lobar pneumonia in the right lower lobe. During the following four days the pulmonary process extended to the remainder of the right lung. He was toxic, distended, cyanotic and delirious and had signs of meningeal irritation, but lumbar puncture yielded normal spinal fluid on two different occasions. On March 3 and 4 he was considerably improved mentally, and the temperature and pulse rate approached normal. Bilateral septic parotitis developed, March 4, which, under treatment with hot applications, apparently drained adequately into the mouth. The temperature and pulse rate, however, rose steadily during the next three days. The patient again became stuporous and increasingly dyspneic and cyanotic and died, March 8. Type I pneumococci were isolated from thick brown mucoid sputum obtained, February 26, and

again from purulent sputum two days later. February 27 and during the succeeding five days, repeated small doses of Felton's serum were given intravenously without apparent benefit. Repeated blood cultures, before and after the serum administration, were sterile. The patient's serum repeatedly showed a large excess of antibodies, even on the day of death. Autopsy revealed complete consolidation of the right lung with many large abscesses containing thick green pus. From these abscesses, from numerous areas in the consolidated lung, and from the parotid abscesses, pure cultures of hemolytic *Staphylococcus aureus* were obtained and no pneumococci could be found.

CASE 6.—E. H., a woman, aged 59, was suddenly taken ill with chills and vomiting, March 29, 1933. Fever, cough and chest pain soon followed. She was admitted to the hospital, April 1. April 2, she first showed signs of lobar pneumonia in the left lower lobe and, successively, abdominal distention, cyanosis, prostration and auricular fibrillation developed. April 6 the temperature dropped by crisis with striking coincident general improvement. The temperature remained normal for twenty-four hours and then again rose steadily. Dyspnea, cyanosis and prostration recurred, and the patient died, April 9. Type VIII pneumococci were obtained from the sputum, April 2. Blood cultures, April 3 and again April 7, were sterile. The serum on April 7 showed a high titer of agglutinins and mouse protective antibodies for type VIII pneumococci, although these antibodies were entirely absent in the serum of April 3. At autopsy there was a resolving pneumonia and fibrinous pleuritis of the left lower lobe, marked tracheobronchitis and patchy consolidation of the right lower lobe. Hemolytic streptococcus in pure culture was grown from the heart's blood and *Staphylococcus aureus* and hemolytic streptococcus, but no pneumococcus, were cultured from the lungs.

These two cases probably represent fatal superinfections, in one instance with staphylococci, in the other with streptococci and staphylococci. In the latter case there was definite immunologic evidence of recovery from the type VIII pneumococcus infection. Another instance will be mentioned, in which the superinfection was with another type of pneumococcus, and the patient recovered.

CASE 7.—D. V. F., a woman, aged 39, was admitted to the hospital, Jan. 7, 1933, following attempted suicide by iodine ingestion. The patient gave a confusing history, but she had definite signs of right lower lobar pneumonia at the time of admission to the hospital. She did not appear very ill and had only a low grade fever. The temperature dropped by lysis, January 8, and remained normal from January 9 to 12, when there was a recrudescence of low grade fever with cough productive of thick brown sputum. She was moderately ill until January 19, when there was a critical drop in temperature with coincident improvement. The signs in the right lower lobe persisted, but no new areas of consolidation were detected in the lung. Type III pneumococci were obtained from purulent sputum, January 8. The thick brown sputum obtained on January 12 showed type VII and no type III pneumococci. Blood cultures made on January 12 and 17 showed no growth. Agglutinins and protective antibodies for type III pneumococci were demonstrated in the serum, January 11 and again January 17 and 26. Type VII antibodies could not be detected in the serum on January 11 and 17 but were found in high titer on January 26.

In this case there is evidence of successive infections with two distinct types of pneumococci and immunologic evidence of the successive antigenic activity of each of these respective types.

A summary of some of the important features in the seven cases cited is given in table 2. These cases have been chosen simply to illustrate some of the different ways in which mixed infections may manifest themselves in different patients.

COMMENT

Brief mention may be made of some of the clinical and epidemiologic implications involved in such mixed infections as have been described here. Clinically, each of the three categories mentioned has a special significance. Practically, their importance is concerned largely with the application of specific therapeutic agents. The efficacy of serum treatment in pneumococcic pneumonia has been shown repeatedly to depend strictly on its type specificity. Correct and rapid etiologic diagnosis is essential for its rational use. It becomes apparent at once that when more than one organism is present it is necessary to recognize, if possible, the rôle played by

in group IV. This matter, however, has been discussed in the literature dealing with bacteriologic studies in pneumonia and with its specific therapy.

That the presence of multiple organisms invading simultaneously or consecutively may complicate the clinical course and outcome of the disease is obvious. That mixed infections can account for certain failures in cases otherwise adequately treated with specific agents is likewise apparent. In a similar manner, these mixed infections may be responsible for relapses in certain instances, after apparent beneficial effects, and sometimes seemingly striking improvement, have temporarily followed the administration of such specific agents. It

each. Likewise, even when only one agent is recovered at first, it is necessary to be aware of the possible errors involved in the methods and of the relative importance of the finding of different organisms or of the various types of pneumococci. Studies¹⁵ of the antibody response of pneumonia patients to infections with different types of pneumococci and comparisons of pneumococcus types found in sputum with those recovered from other sources in the same patient have indicated that certain types, such as types I, II or V, are more apt to be etiologically significant than others, particularly type III and certain of the types formerly classified

is necessary, therefore, to think of the possibility of mixed infection or superinfection in pneumonia whenever one is concerned with an unusually prolonged acute illness, or when there is a recurrence of acute symptoms after apparent improvement. To be sure, focal purulent complications are the commonest cause of such irregularities in the course of or during convalescence from pneumococcic pneumonia, but the possible presence of other invaders should be kept in mind and will explain some puzzling cases.

Epidemiologically, the cases of mixed infection have a special significance. Repeated investigations have shown that the virulent types of pneumococci and those most frequently associated with primary acute pulmonary infections can be recovered only rarely from nor-

mal mouths. Except in rare instances of chronic carriers, such organisms are found as transient inhabitants of normal throats, usually in persons who have had some contact with cases of the same type. Furthermore, the frequent occurrence of virulent pneumococci associated with colds, particularly when pneumonia is prevalent,¹⁶ and the frequency of antecedent acute infections of the upper respiratory tract in patients with pneumococcal pneumonia indicate that persons with mild infections may acquire virulent pneumococci and become sources of pulmonary infections in themselves and to their contacts. That mixed infections and superinfections arise from without, in a manner similar to the usual primary pneumococcal pneumonias and not simply as autoinfections due to lowered resistance, is clearly shown by the observations made by Opie, Blake, Small and Rivers⁴⁶ in their studies on epidemic respiratory infections at Camp Pike. This was demonstrated for superinfections with pneumococci as well as with virulent hemolytic streptococci. The observations of these investigators and those mentioned in other epidemiologic studies indicate clearly the importance of isolating cases of pneumonia, especially in crowded wards and during unusual prevalence of respiratory disease.

SUMMARY AND CONCLUSIONS

Certain features of a group of 133 cases of pneumonia associated with two or more pneumococcus types or with pneumococci and other organisms have been brought out by referring to illustrative cases.

The cases fall into three groups: (1) cases in which one organism is the effective invader and the other organisms are incidental; (2) cases of concurrent infections, and (3) cases of consecutive infections.

It is important, for purposes of therapy and prognosis, to recognize the presence of mixed infections and to evaluate the relative importance of the various organisms found.

Boston City Hospital.

ABSTRACT OF DISCUSSION

DR. W. D. SUTLIFF, Chicago: The data that Dr. Finland has presented illustrate the usefulness of accurate bacteriologic examinations in pneumonia. As a result of frequent determinations, changes in the clinical course are more easily explained and complications are really traced to their sources. From a clinical point of view, this particular application of bacteriologic study of pneumonia cases should appeal to every one. Other reasons for studying pneumonia bacteriologically have been presented from time to time. The first of these is to choose patients for type-specific antipneumococcus serum therapy. As is well known, a small proportion of the total number of cases of pneumonia are susceptible to specific therapy, and determination of the type of pneumococcus is essential to the discovery of such cases. A second use for bacteriologic information in pneumonia has to do with the question of the precaution that may be necessary to prevent spread of the infection. The degree of isolation of pneumonia patients varies widely. In certain hospitals extreme measures are used to protect pneumonia patients from visitors, from physicians and from other patients. In other hospitals no precautions are used. A recent investigation by Smillie and Leader in Boston, in which two different hospitals were compared, has thrown light on this situation. In one hospital it was difficult to find organisms of the same type as those of the patients among the attendants. The infecting pneumococcus strain was found among attendants about as often as it was in the general population. In another hospital, in which a patient with type I pneumonia had developed

an empyema and was being tapped frequently, the spread of organisms was very obvious. The type I pneumococcus was found in the throats of those who were in contact with the patient and in one instance led to a second infection. Thus a more thorough understanding of the circumstances in which one needs to take care to prevent the spread of virulent pneumococci is being evolved by means of careful bacteriologic work. In the classification of pneumonia it has been found that the various organisms differ to a certain extent in the sort of pneumonia they produce. Lobar pneumonia is produced by the more virulent types I and II. Bronchopneumonia is produced by the less virulent pneumococcus, streptococcus, staphylococcus and Friedländer's bacillus. Bronchopneumonia is almost entirely a secondary disease, secondary to debilitating disease, to operation and to previous infections. In the cases that Dr. Finland has reported, it is fairly obvious that lobar pneumonia itself may be classed as one of the precursors of a secondary pneumonia or bronchopneumonia. Such secondary infections can be fully understood clinically only through repeated bacteriologic examinations.

DR. MAXWELL FINLAND, Boston: I thank Dr. Sutliff, who was associated with the largest part of the work here presented, for his discussion. There is one point I might raise in regard to the importance of some of the infections we have observed since these data were accumulated. In the first two weeks of May, of ten consecutive autopsies on pneumococcal lobar pneumonia, six were complicated with hemolytic streptococcus. I was interested to read a recent report to the effect that measles was more frequent this year than it has been for the past thirty years. Hemolytic streptococcal infections complicating lobar pneumonia were very prevalent during the war in the army camps in this country, especially during measles epidemics. Such cases were studied carefully by Cole and McCallum and were reported before this association in 1918 and 1919. There may be some relationship between the high frequency that we have recently observed of hemolytic streptococcal infection following lobar pneumonia and the high prevalence of measles this year throughout the community.

ECTOPIC PREGNANCY

OBSERVATIONS IN ONE HUNDRED AND THREE
CASES SEEN IN PRIVATE PRACTICE

CHESTER M. ECHOLS, M.D.

MILWAUKEE

In the course of a general surgical practice of thirty years I have operated in 103 cases of ectopic pregnancy,¹ not including a few cases of hematosalpinx of uncertain origin. The operations were done in various Milwaukee hospitals, in smaller outlying hospitals and, a few of the earlier ones, in cases in which it was deemed inadvisable or unsafe to transport the patient, in private homes in the country.

All the patients were white women and all were private patients; that is, none came from clinics or outpatient departments. The predominant age was from 25 to 35 years; the oldest patient was 43.

Four cases were twin pregnancies; all unilateral. There was no case of concurrent intra-uterine and extra-uterine pregnancy. Two were abdominal pregnancies of from six to seven months. Ovarian pregnancy, interstitial pregnancy, and lithopedion formation were not encountered in the series. In no case was there a rupture into the broad ligament.

In one instance the pregnancy was in the rudimentary horn of a bicornate uterus.

Read before the Section on Obstetrics, Gynecology and Abdominal Surgery at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 15, 1934.

¹ The first thirty-seven of these cases were previously reported: Echols, C. M.: Wisconsin M. J. 15:408 (April) 1917.

16. Smillie, W. G.: Epidemiology of Lobar Pneumonia: A Study of the Prevalence of Specific Strains of Pneumococci in the Nasopharynx of Immediate Family Contacts, J. A. M. A. 101:1281 (Oct. 21) 1933.

Three of the women were widows and two had never been married, a fact of slight importance, except as regards the matter of diagnosis.

One patient subsequently became pregnant in the remaining tube. So far as I could learn, this was the only recurrence in the entire series. None of the patients died. With the exception of one woman, in whom a pelvic abscess developed and who was in the hospital five weeks, all were able to leave the hospital in from eleven to fourteen days.

For statistical study, there are available in the literature reports of many series of hundreds of cases of ectopic pregnancy. For completeness of data, the series reported from the Johns Hopkins Hospital embracing all cases at that hospital since 1890 is one of the best.² Hawks'³ compilation of 824 cases from New York is one of the most comprehensive on the subject. It must not be forgotten, however, that these large lists, after all, represent the work of many operators of varying degrees of ability, employing different technics and possibly having conflicting opinions as to when to operate. The results obtained in such a composite collection of operations may well fall short of what could be expected if one surgeon did all the operating. The large personal experience of Polak,⁴ Oastler⁵ and Hendry,⁶ lends great interest to their reports and weight to their opinions, even though their records may be less complete statistically than the larger compilations.

OBSERVATIONS IN 103 CASES

Observations suggested by my own series of 103 cases may be conveniently discussed under the following headings:

Incidence.—The ratio of extra-uterine pregnancies to births can be determined with reasonable accuracy by dividing the total number of births in a given city or area by the total number of ectopic pregnancies in the same area. Thus, in the year 1933, the total number of births (including stillbirths) in the county of Milwaukee was 13,251. During the same year fifty-nine cases of ectopic pregnancy came to operation in all the hospitals in the county. Two of the fifty-nine cases originated outside of the county, leaving the net total number fifty-seven. The ratio of ectopic pregnancies to births was therefore 1 to 250 in Milwaukee County for the year 1933.

By a similar calculation Schumann⁷ found the ratio to be 1 to 267 in Philadelphia for the year 1918. This method of figuring does not take into account the unknown percentage of intra-uterine pregnancies that terminate by abortion and are not reported to the health authorities, nor the ectopic pregnancies in which recovery occurs without operation or diagnosis. Since economic and social conditions affect the abortion rate as well as the birth rate, it is obviously impossible to give any estimate of the percentage of abortions applicable to all times and localities. My impression is that ectopic pregnancies are relatively, if not actually, increasing.

Previous Gonococcic Infection.—Early in the century Schauta, Hahn⁸ and other workers in large European

clinics assigned to gonorrhea the major rôle in the causation of tubal pregnancy. Writers of textbooks copied their statements and have passed them along down to the present day. My own observations fail to confirm the prominent part assigned to the gonococcus. Only two women in my series gave a clearcut history of gonorrhea, and half a dozen others gave histories suggestive of a former gonococcic infection. This opinion is expressed with the full realization that a woman may have gonorrhea without being aware of it. Engelmann⁹ is convinced that the increasing incidence of ectopic pregnancy is due to abortion rather than to gonorrhea, an opinion in which I heartily concur.

Previous Operations and Abortions.—Twenty-eight women of this series had had previous abdominal operations or abortions. These figures are significant when one considers that abortions and abdominal operations may be productive of salpingitis or pelvic adhesions with distortion of the tubes; conditions that predispose to tubal implantation of the ovum.

Age and Social Status.—The age range was from 22 to 43 years, the large majority being between 25 and 35.

As previously stated, five of the women were either unmarried or widows. This fact is mentioned only as a reminder that one must not be unduly influenced by the social status of the patient in seeking a correct diagnosis.

Sterility.—None of my patients had borne more than three children prior to operation, and only four of them had borne that number. Previous total sterility was fairly common, but by far the largest group fell in the category of one-child sterility for a period of years preceding the ectopic pregnancy. In two of the patients tubal pregnancy developed while they were nursing babies aged 5 and 6 months, respectively.

In contrast with my own experience and that of most other observers, it is interesting to note that Polak reported a number of cases of tubal pregnancy among poorer immigrant women of New York and Brooklyn who had borne numerous children in rapid succession, while Hendry reports a remarkable case of tubal pregnancy from the Montreal General Hospital. The patient, aged 35, had gone through fourteen full term pregnancies and had had twelve abortions.

Menstrual Anomalies.—Menstrual anomalies of one kind or another were observed in slightly more than three fourths of the patients. The commonest form was as follows: After a period had been missed for from two days to a week or more, flowing began and continued for weeks, accompanied by occasional lancinating pelvic pains. Many women in this flowing stage have been curetted, usually with a diagnosis of incomplete abortion. In no case in my series did the curettage produce more than a temporary check to the flow.

Uterine bleeding in tubal pregnancies is much less profuse than in real abortions—an important point in differential diagnosis which, it seems to me, has not been sufficiently emphasized.

About 20 per cent of my patients had no warning menorrhagia or uterine bleeding. In this group are included those cases of early tubal perforation and violent intraperitoneal hemorrhage with collapse.

Vaginal bleeding in ectopic pregnancy is usually interpreted as meaning that the embryo is dead and that shedding of the uterine decidua has begun, but in those

cases of early, sudden tubal perforation with massive intraperitoneal bleeding, collapse comes before the uterus has had time to begin shedding its decidua.

Tubal Abortion and Tubal Rupture.—Tubal abortion, partial or complete, occurred about four times as often as rupture of the tubal wall. To avoid confusion of terms, I am limiting the expression "ruptured tubal pregnancy" to cases of gross rupture or perforation of the tubal wall. The early destruction of the delicate gestation sac and escape of the ovum (internal tubal rupture of Litzenberg) is really more analogous to abortion, and I prefer to look on it as a variety of tubal abortion. In this restricted sense, rupture occurred in slightly under 20 per cent of the cases in this series. The bleeding in the ruptured cases was generally but not invariably enough to cause immediate pallor and collapse.

Of the unruptured cases diagnosed before operation, three presented no other palpable evidence than a tender fusiform enlargement of the tube the size of a hazelnut close to the cornu. The thin and flaccid abdominal wall made it possible to diagnose tubal pregnancy in these three cases by bimanual palpation. Ordinarily it is not possible to make such an early diagnosis.

Contrary to the commonly accepted teaching, I found that four of the most dangerous cases of hemorrhage were caused by perforation in the outer half of the tube.

Abdominal Pregnancy.—In my series there were two cases of abdominal pregnancy. In each case the fetus had died at about the end of the sixth or the first half of the seventh month. Since both fetuses died from two to four weeks prior to operation, there was no troublesome hemorrhage in dealing with the placenta. These cases are believed to have originated as tubal pregnancies. In one of them a portion of the placenta was still attached to the mucosa of an enormously distended fallopian tube; in the other the placenta was attached to various structures up as high as the liver.

Multiple Pregnancies.—In each of the four cases of twin pregnancy encountered in this series, the twin fetuses were in the same gestation sac. Although the literature abounds in isolated reports of concurrent extra-uterine and intra-uterine pregnancy and of bilateral tubal pregnancy, I have not yet seen any of this type.

Pregnancy in a Rudimentary Horn of a Bicornate Uterus.—The one case of pregnancy in a rudimentary horn of a bicornate uterus occurring in my series behaved in every way like a sudden rupture of a pregnant tube with massive hemorrhage. When brought to the hospital in shock and collapse, the patient gave a history of having one healthy child, aged 3½ years. The delivery had been normal. She had missed the last three menstrual periods. Immediate laparotomy revealed an enormous amount of fresh blood and a fetus of about fourteen weeks, attached to a cord lying among the intestines. The frayed-out placenta indicated that the pregnant rudimentary horn broke with explosive violence. The operation consisted of amputating the rudimentary horn with the attached ovary and tube.

Examination of the specimen disclosed two interesting facts: (1) There was no corpus luteum in the ovary removed, and (2) the rudimentary horn had no canal communicating with the cervical canal. This meant, of course, that a sperm had traveled up through the tube on the opposite side and had fertilized an ovum from the ovary of that side, and that the fertilized ovum had then been picked up by the tube

attached to the rudimentary horn. This was, therefore, a clearly demonstrable case of external migration of the fertilized ovum, and not one of external migration of spermatozoa.

Recurrence.—Five years after the removal of a pregnant right tube, one woman in this series came back with a pregnant left tube. It is rather surprising that this is the only instance of recurrence that I have observed in the 103 cases. Some writers have found recurrences in as high as from 4 to 10 per cent of their cases. Of course, it might be argued that there may have been subsequent ectopic pregnancies in the patients of this series who were operated on by other surgeons. It seems more likely, however, that I would have heard about such operations through my colleagues, if not from the patients themselves.

Diagnostic Errors.—Correct diagnosis before operation was made in between 70 and 80 per cent of the cases. A more complete and detailed history in all cases would have raised the percentage of correct diagnoses. On three occasions, to my knowledge, I have examined women with extra-uterine pregnancy without recognizing the condition. Later, when the symptoms were more pronounced, the patients were operated on by other surgeons. Errors of this type must be included if a close check is to be kept on all mistakes. Five times I have operated for ectopic pregnancy without finding it. No particular harm was done by this sort of error, for in each case some other condition was found that called for surgery.

One of my failures to recognize a tubal pregnancy was in the case of a woman, aged 42, who, ten months previously, had received an intra-uterine radium treatment for menorrhagia due to fibrosis in an enlarged uterus. The purpose of the radium treatment was to shrink the enlarged uterus and bring about the menopause. The treatment apparently was a complete success, for when I saw her ten months later because of a slight pain in the right lower quadrant, she had not flowed at all since the radium treatment. I thought the slight pain was probably appendical. Three weeks later another surgeon removed a pregnant right tube.

Two other failures to diagnose tubal pregnancy before operation occurred in women who were nursing babies of 5 and 6 months and who, therefore, had not menstruated for the preceding fourteen or fifteen months.

A surprisingly large number of my earlier patients had been diagnosed as bleeding from incomplete abortion, and curettage had been done with the idea of emptying the uterus of retained secundines. Curettage invariably failed to cure such uterine bleeding. A careful history and physical examination will nearly always differentiate between extra-uterine pregnancy and ordinary abortion without resort to curettage. The greater severity and shorter duration of hemorrhage in abortion is one important differential point.

Hormone tests, such as the Aschheim-Zondek, have been disappointing. The extra-uterine embryo is usually, if not always, dead before vaginal bleeding begins. Since hormone tests become negative soon after the death of the embryo, they are apt to fail when they are needed most.

Failure to think of the possibility of ectopic pregnancy in a given case is one of the commonest causes of failure to recognize it.

Finally, there is no constant unfailing sign or symptom of ectopic pregnancy. Its pathology is too varied

to be reduced to a formula. For this reason it is doubtful whether the time will ever come when more than three fourths of all cases will be correctly diagnosed before operation.

Operative Measures.—Lawson Tate, just fifty-one years ago, was the first man to operate deliberately for ruptured ectopic pregnancy.

Among surgeons of today there is no serious difference in the procedure, except in dealing with the condition that some writers are fond of calling "tragic cases" of rupture, rapid hemorrhage and collapse. When in 1907 the late Hunter Robb advocated waiting for such patients to recuperate from the shock of hemorrhage before operating, he precipitated a controversy that has not completely subsided to this day. He rightly argued that death rarely comes from the first hemorrhage following rupture, and counseled waiting for improvement before operating.

Convincing evidence, however, has accumulated that patients with ruptured tubes can, and do, bleed to death. In the desperate cases, which constituted about 15 per cent of my own series, I made it a rule to operate quickly if there was a breath of life in the patient, and to stimulate during and after operation. It is worse than a waste of time to mop the abdominal cavity dry. I removed only the large masses of clot and then the abdomen was filled with salt solution while the peritoneum was being closed.

Drainage was employed only three times in this series. Colpotomy was done only twice, and then only because of a wrong diagnosis. Puncture of the vaginal vault is neither a desirable nor an accurate method of diagnosing ectopic pregnancy.

Mortality.—The fact that all of the 103 women of this series, including an average proportion of "tragic" cases, recovered completely following their operations is eloquent testimony to the recuperative power of this class of patients. These women are usually in the prime of life and are among the most promising risks in the whole field of major surgery.

231 West Wisconsin Avenue.

ABSTRACT OF DISCUSSION

DR. JOSEPH D. HEIMAN, Cincinnati: The ratio of ectopic pregnancies to the total number of births is interesting. Another way of determining the incidence is in relation to the total number of gynecologic cases. With an average turnover of about 1,300 a year in the Cincinnati General Hospital there are approximately fifteen ectopic pregnancies, or a ratio of 1 to 78. I am glad that Dr. Echols disagrees with the prescribed teachings of gonorrhea as a causative factor. There was no history or evidence of this infection in a series of thirty cases that I reviewed in 1932 and 1933, whereas a number of these patients had abortions previous to their ectopic pregnancies. The chief symptoms are still menstrual anomalies of one kind or another and one-child sterility. I differ slightly in my method of treatment in that I try partially to overcome the shock before operation, by means of blood transfusion. I have never failed to produce some degree of improvement. During the operation, if time will permit, I suck out as much fluid blood as possible, filter it and introduce it into the patient's vein. As much as 1,200 cc. has been given in this way. A very important point brought out is that vaginal bleeding in tubal pregnancy is much less profuse and of longer standing than in real abortions. In sudden rupture, vaginal bleeding may be absent. Tubal abortion is a much less serious accident than tubal rupture. If one could be sure of the type with which one is dealing, one could allow the condition to improve before doing an immediate operation. These are the cases that present recurrent attacks of pain, bleeding and then recovery.

It is when the clot can no longer hold the pregnancy in the tube that profuse fatal bleeding may occur. In the rupture of the tubal wall, however, there is no temporary stoppage of bleeding. Dr. Echols' single recurrence reminds me of a case in which a right tubal pregnancy occurred two years after a previous tubal pregnancy on the same side. The first surgeon had not completely removed the tube at the time. So far as I know this is the only case in which two pregnancies have occurred in the same tube.

DR. JOSEPH B. DE LEE, Chicago: I should like to know what your treatment is of ectopic gestation that has ruptured and the patient when you first see her is in a moderate or even a considerable degree of shock. I am therefore going to make a proposition and ask you to vote on it. How many will operate at once in a diagnosed ectopic pregnancy in which the patient enters the hospital in shock?

DR. EMIL NOVAK, Baltimore: You ought to qualify that—with transfusion at the time.

DR. DE LEE: Well, I will put it this way: If the woman is in shock, the first thing one does is to give her blood and salt solution and sugar, but one makes immediate preparations for operation and operates. How many do that and how many prefer to follow the recommendation of Hunter Robb many years ago, of waiting for the shock to disappear before operation? Those who are in favor of immediate operation please say "aye." How many prefer to wait until the shock has gone?

DR. NOVAK: Hunter Robb, as I understand it, advocated in a very large percentage of cases conservatism in the management of these cases.

DR. DE LEE: I think the issue is clearly defined and I am not criticizing Hunter Robb. How many prefer to wait until the shock is over or, to put it even more drastically, how many wait in any case of ectopic pregnancy whether the symptoms are mild or severe? Say "aye." [All said aye.] I feel that, when a diagnosis of ectopic pregnancy is made, immediate operation should be performed and one should not wait until the next morning either, even if the symptoms are mild. I am glad to see that the majority agree with me.

DR. W. H. WEIR, Cleveland: As an assistant to Dr. Hunter Robb, I was privileged to help in his research to which Dr. Echols referred. Dr. Robb found that it was practically impossible to kill a pregnant bitch by dividing and leaving untied the uterine arteries, even if the abdomen was reopened an hour or so later to start the bleeding anew. One cannot argue that the same could be done in a human being, but it does show the ability of the organism to overcome a tremendous loss of blood. There is no question that most of the fatalities in ectopic cases in those days were due to the patients' being operated on in severe shock. Transfusion was seldom employed, as the technic was far more complicated and difficult than it is now. Blood grouping was unknown and bad results occasionally happened. The ease and rapidity with which blood transfusion can be performed today has decided the whole problem of that time as to whether to operate immediately, before the patient might bleed to death, or to wait in the hope that the hemorrhage might cease and the patient recover from the severe shock, which she will do almost always without blood transfusion. There is no condition in gynecology which so often leads to mistakes in diagnosis as ruptured ectopic pregnancy. I have made many errors. Pus tubes may be far more suggestive of ruptured ectopic and vice versa, and all the clinical signs and the laboratory aids to diagnosis, such as the leukocyte count and the sedimentation test, may indicate the wrong diagnosis. In one unusual case a thin-walled ovarian cyst, presumably a follicular retention cyst, was felt to rupture during examination, a relatively common experience and unattended by any ill results as a rule. The history in this case had been a little suggestive of ectopic pregnancy, so the patient, who was in the hospital, was carefully watched. No trouble occurred until about fourteen hours later, when she quickly went into profound shock. Transfusion was done and the patient immediately operated on for a supposed ruptured ectopic pregnancy. No blood was found in the abdominal cavity, only a quantity of chocolate-colored fluid from a ruptured endometrial cyst. The gradual absorption of this fluid apparently produced a toxemia with the clinical picture of severe shock.

OXYGEN IN THE TREATMENT OF ACUTE CORONARY OCCLUSION

ALVAN L. BARACH, M.D.

AND

ROBERT L. LEVY, M.D.

NEW YORK

In a previous communication¹ we reported that the administration of 50 per cent oxygen to certain patients suffering from coronary thrombosis sustained cardio-respiratory function during a critical period and made possible their ultimate recovery. Because the importance of this measure has not been recognized in a number of recent articles and textbooks, further evidence in support of our original conclusions is presented and the technic of oxygen therapy outlined in detail.

When a coronary branch is suddenly occluded, the area of myocardium normally supplied by this vessel is abruptly deprived of blood. The function of the affected muscle is impaired because of lack of nutrition, especially through want of the oxygen necessary for normal contraction. If a sufficiently large area is involved, the heart is no longer able to empty itself of the customary volume of blood and the pressure in the auricles and veins increases. Passive congestion is thus produced in the lungs and viscera. Pulmonary function with respect to the absorption of oxygen becomes impaired, since oxygen does not diffuse readily through edematous alveolar walls. The volume of air in the lungs is diminished by the increased amount of blood in the congested pulmonary vessels. Loss of pulmonary distensibility prevents adequate ventilation. The blood passing through the lungs is incompletely aerated and the heart is consequently provided with arterial blood deficient in oxygen. Its activity is thus further handicapped.

As the result of this sequence of events, a vicious circle is initiated which induces progressive oxygen starvation of the heart muscle. That the myocardium is particularly sensitive to this condition was shown in an experimental study by Katz and Long.² They demonstrated that increasing oxygen want caused an exhaustion of the heart muscle when the lactic acid content was elevated to two and a half times the normal level, whereas skeletal muscle was able to contract until the lactic acid reached four and a half times the resting content.

In two cases of heart failure, Beddard and Pembrey³ in 1908 observed that the inhalation of oxygen caused a marked decrease in pulmonary ventilation. A similar effect, with subjective improvement, was noted by Campbell and Poulton.⁴ In 1921, Barach and Woodwell⁵ showed that the arterial and venous oxygen saturations of patients with congestive failure could generally be substantially elevated by the inhalation of from 40 to 60 per cent oxygen. In 1929, Barach,

Richards, Milhorat and Levy⁶ reported that certain patients with advanced cardiac insufficiency who had failed to respond to other forms of treatment were restored to compensation by continuous oxygen therapy, given for from two to six weeks. In the cases that improved, the noteworthy features were relief of dyspnea, occurrence of diuresis and marked elevation of the carbon dioxide content of the arterial blood. These results were in part confirmed by Hamburger, Katz, Cohn and Rubinfeld.⁷ In studying the oxygen consumption of patients with cardiac failure, Uhlenbruck⁸ noted a temporary increase in oxygen absorption when oxygen was inhaled instead of air. This observation was repeated by Jansen, Knipping and Stromberger,⁹ who termed the increment of absorbed oxygen the "oxygen deficit." The patient with cardiac insufficiency was thus shown to be continuously short of oxygen.

That the pain of acute coronary occlusion might be relieved by inhaling oxygen in high concentration was first pointed out by Rizer.¹⁰ Lewis¹¹ showed that pain results when the blood supply to a working muscle is inadequate and inferred that attacks of anginal pain are brought about by relative ischemia of the heart muscle. Kissin,¹² going a step further, demonstrated that oxygen want is the chief contributing cause of pain in an exercised muscle. With Rothschild, Kissin was able to induce attacks of anginal pain by lowering the concentration of oxygen in the air breathed by patients with coronary sclerosis.¹³ Conversely, Barach¹⁴ reported that individuals who suffered from repeated attacks of cardiac pain obtained definite relief while in residence in an oxygen chamber.

The facts just enumerated establish three points: 1. Anoxemia of the heart muscle occurs after sudden occlusion of a sizable coronary branch. 2. Oxygen want induces impairment of cardiac and respiratory activity. 3. The inhalation of oxygen, in high concentration, increases the oxygen content of the arterial blood and results in improvement in the functional capacity of the heart.

The beneficial effects of oxygen treatment in cases of coronary thrombosis have been confirmed in clinical reports by Ulrich,¹⁵ Kilgore¹⁶ and Bickel.¹⁷ A dramatic instance was recorded by Burgess, Briggs and Burgess:¹⁸

A woman, aged 66, became pulseless and cyanotic following an acute attack. The blood pressure was not obtainable. Characteristic electrocardiographic changes were found. Oxygen was given by the "open box" method at the rate of 7 liters

a minute. At the end of three hours, the cyanosis had disappeared and the pulse was of good quality. The patient ultimately recovered.

The group of sixteen new cases that we have studied is not sufficiently large for statistical presentation. The results, however, have confirmed our earlier impressions and, in the cases which have responded favorably, may be summarized as follows:

1. Subjective improvement occurred in from one to three hours after the administration of oxygen was begun. The relief of pain was striking. Respiration became less labored and slower. The patient was no longer restless. It was therefore possible to curtail materially or even stop entirely the use of morphine and other sedatives.

2. Cyanosis was diminished or abolished.

3. Cheyne-Stokes breathing, if present, gradually disappeared.

4. The temperature, in cases in which it was elevated, tended to fall.

5. The heart rate became slower. The heart sounds grew stronger and the volume of the pulse improved. The signs of congestion in the lungs became less marked. As the state of the circulation improved, the arterial blood pressure rose and the venous pressure fell.

6. Interruption of oxygen therapy before adequate readjustment of circulatory conditions had taken place resulted in recurrence of the symptoms and signs just cited.

It is not to be expected that all these beneficial effects will take place in every case. When one of the larger vessels is occluded, particularly if the heart muscle is already seriously damaged, recovery may not be possible. It is frequently difficult to foretell the outcome. We have been surprised to observe improvement in cases that seemed to offer but little hope of a favorable course. In other patients, a sudden turn for the worse has resulted in death at a time when the prognosis seemed good. The use of oxygen does not appear to prevent extension or recurrence of the thrombotic process, but it does lighten the burden thrown on a myocardium that has received a sudden, damaging shock. Thus, during the period of greatest stress, it affords an added margin of safety, which may be sufficient to enable the heart to recover.

During the acute phase we have come to depend less and less on drugs, with the exception of morphine. The value of digitalis or caffeine at this time is debatable. A paroxysm of ventricular tachycardia can usually be terminated by quinidine. A discussion of other details of management may be found in current monographs.

METHOD OF OXYGEN TREATMENT

Not every case of acute coronary occlusion requires oxygen therapy. Patients who suffer from the milder forms¹⁹ may experience only brief discomfort and may make a rapid symptomatic recovery. On the other hand, the potential gravity of the condition and the abruptness with which circulatory failure may develop make it desirable to provide for the availability of oxygen on short notice, as soon as the diagnosis is made. It is well to pursue a policy of watchful waiting and to begin oxygen when evidences of impairment in cardiorespiratory function first become apparent. The presence of cyanosis is the classic index of oxygen want, but it cannot be trusted too far. An ashen gray

color or pallor may be observed even in the presence of relatively severe anoxemia, since capillary constriction, due to shock, may prevent sufficient blood from reaching the skin to transmit the bluish tint. The clinical picture serves as the best guide. Rapid heart rate, feeble heart sounds, often with gallop rhythm, labored breathing, persistently low blood pressure and moist râles at the bases of the lungs are signals of distress from a failing circulation which needs support.

The most effective way of giving oxygen is by means of a large, well ventilated tent.²⁰ The temperature inside the tent should generally be kept between 60 and 65 F., since at these levels most patients experience the greatest comfort. A concentration of 50 per cent oxygen is usually employed; 60 per cent can be given indefinitely without harm. In severe cases with rapidly progressive failure, 70 per cent concentration may be used for several hours at a time. Mixtures containing over 70 per cent are not recommended except for brief periods, for in animals such high concentrations have been found to be irritating to the lungs when administered continuously for a number of days. The aim of therapy is to maintain a degree of concentration sufficient to overcome the existing anoxemia.

On the average, it is desirable to keep the patient in the tent for about five days. This period may be shortened or extended, depending on the condition. It must be borne in mind, however, that the satisfactory and comfortable appearance of the patient may be due to the sustaining effect of inhaling a mixture rich in oxygen. For this reason, it is advisable to lower the oxygen concentration gradually from 50 to 35 per cent over a twenty-four hour period, then to 21 per cent during the following twelve to twenty-four hours. If it is desired to stop oxygen without previous lowering of the concentration, the patient should be carefully observed after removal of the tent, for signs of dyspnea and cyanosis. The pulse and respiratory rate should be counted at fifteen minute intervals for three hours. If the heart rate does not increase more than ten beats a minute above its rate in the tent, and the respiratory rate does not rise more than six a minute, oxygen may be discontinued. If such an acceleration in either cardiac or respiratory rate should occur, it is safer to continue treatment for another day and then stop the oxygen, the same observations being made.

An oxygen chamber is, of course, a more comfortable method of therapy, but it is available only in a hospital. A portable chamber,²¹ made of rubberized fabric, can be brought to the home and affords a sense of greater spaciousness. It is more troublesome to set up and more costly to maintain.

If a tent or chamber is not available, the nasal catheter may be employed as a measure of moderate effectiveness. The oxygen should come from a high-pressure tank and be given through a calibrated gage at the rate of from 5 to 6 liters a minute. This provides about 38 per cent oxygen, if the patient breathes through the nose. By placing the catheter beyond the posterior pharynx, so that the tip rests just above the glottis, Wineland and Waters²² have found that a flow of from 7 to 8 liters per minute is capable of maintaining a concentration of 50 per cent. This is the rate of flow ordinarily employed in supplying a

tent. A few patients that we have treated by this method complained of irritation of the throat, and a hacking cough necessitated withdrawal of the tube. The method is undoubtedly of value, but the throat must be sprayed frequently with liquid petrolatum.

SUMMARY

Anoxemia of the heart muscle occurs after sudden occlusion of a sizable coronary branch. General oxygen want results and induces impairment of cardiorespiratory activity. The inhalation of oxygen, in high concentration, increases the oxygen content of the arterial blood and results in improvement in the function of the heart.

On the basis of these facts, oxygen has been given, usually in a concentration of 50 per cent, to a series of patients suffering from the effects of acute coronary occlusion. In a considerable number, both in our own experience and in that of others, great symptomatic relief has been afforded. We feel justified in concluding this report, as we did the paper published in 1930, with these words: "Employment of oxygen therapy may aid in maintaining an adequate circulation until the heart has had an opportunity to recover from its acute functional disturbance. Obviously, the cardiac injury may be so severe that recovery is impossible. But in certain instances, effective use of oxygen may be responsible for the saving of life."

ABSTRACT OF DISCUSSION

DR. WALTER M. BOOTHBY, Rochester, Minn.: Whenever a patient has anoxemia of the acute type of any of the tissues of the body due to interference with the oxygen diffusion through the lungs, oxygen therapy is always indicated. Pulmonary edema of any type that is acute is always relieved by the use of oxygen. In the cases of chronic cyanosis and chronic conditions there is comparatively little hope of obtaining any material improvement from temporary use of oxygen. The authors have been interested in keeping some cases under oxygen therapy of various types for months at a time. That is an interesting research problem. I do not believe that hospital facilities for oxygen therapy at present permit of a prolonged monthly use of oxygen in a large series of cases. It ties up too much equipment and the results are, on the whole, too doubtful. But in any form of acute anoxemia, whether cardiac or pulmonary in origin, patients will be helped and benefited and a certain percentage of lives will be saved by the conservative and proper use of oxygen therapy.

DR. A. CARLTON ERNSTENE, Cleveland: The primary aim in the treatment of patients with coronary occlusion is the relief of pain. It is difficult to evaluate the effect of oxygen in shortening the duration of pain, but instances have been recorded that are striking. Kilgore, for instance, reported a case in which the patient was relieved of pain during the time he was kept in an oxygen tent, but the pain promptly returned when oxygen therapy was stopped temporarily. I believe therefore that, whenever the pain of acute coronary occlusion is not relieved with reasonable promptness by large and repeated doses of morphine, one should proceed to the use of oxygen. Aside from the use of morphine, drugs are of little value. A few instances have been reported of prompt cessation of pain following the intravenous administration of theophylline-ethylenediamine. This drug in my own experience, however, has been quite disappointing. The second aim in the treatment of coronary occlusion is support of the circulation. In a majority of the cases, adequate rest in bed is all that is required after the pain has been relieved. In cases, however, in which symptoms and signs of congestive myocardial failure develop or in which persistent auricular fibrillation occurs, the administration of digitalis is indicated. If digitalis does not effect relief of the symptoms and signs of congestive failure, or if acute pulmonary edema develops, one should be prepared

to administer oxygen. I believe that the use of oxygen in these particular situations will frequently give gratifying results.

DR. FORD HICK, Chicago: Dr. Herrick made well known the clinical picture of coronary thrombosis about twenty-two years ago. I want to attest further the effectiveness of the therapy that the authors have outlined. Physicians who have watched these patients die about six hours after the attack feel keenly that anything which will tide them over that period is well worth while. Why the textbooks should not recognize its importance and effectiveness is hard to understand. Surely it must be because the men who write textbooks on therapeutics rarely see the cases in the clinical wards. The effectiveness of oxygen in certain of these cases is little short of miraculous. I would like to attest again the effectiveness of the use of the nasal catheter. As a matter of clinical application, I found that the inspired air contains about 42 per cent of oxygen when administered with the tip of the nasal catheter resting on the top of the soft palate, as Waters recommends.

DR. LOUIS F. BISHOP JR., New York: One important point is the fact that oxygen therapy will often relieve pain when morphine will not. All physicians who have had the experience of not being able to relieve the pain in a case of acute coronary thrombosis realize the value of having some other adjunct. At Bellevue Hospital we have used oxygen therapy in coronary thrombosis in a number of cases. Unfortunately, we do not have the elaborate apparatus the authors have described, such as oxygen chambers and tents, and have not been able to keep the patients in over long periods of time. We have, however, used the nasal catheter as Dr. Ernstene has also reiterated, often with pleasing results. For that reason I hope that more physicians will use oxygen in coronary thrombosis, particularly because it will make it unnecessary to give huge doses of morphine to control the pain.

DR. MARTIN FRIEDRICH, Brooklyn: I would emphasize the use of extremely high oxygen concentrations in anoxemia, whether of cardiac or of pulmonary origin. In reading and hearing the report of the authors, one notes that they always emphasize that one should never exceed 70 per cent, because animals kept in small oxygen chambers succumb to a serious pneumonia after about the seventh or eighth day. Experiments have been done by R. R. Sayers in which animals have been kept at 100 per cent concentrations, or as close to it as is physically possible, for various periods of time. One group of animals was exposed for sixteen hours daily for fifty consecutive days without apparent harmful effects. I would take this opportunity to report a case of a woman who had just been delivered and who suddenly developed a pulmonary embolism. Cyanosis was extremely intense. She was put in a well ventilated, large oxygen tent and the concentration raised to 60 per cent. The cyanosis and dyspnea still persisted and the patient remained quite uncomfortable. Not until the concentration was elevated to 95 per cent was the patient made comfortable. Concentrations of between 80 and 95 per cent were maintained continuously for a period of six days. On the sixth day we were able to reduce the concentration to 60 per cent. Two days later we removed the patient from the tent, with complete recovery. As regards the use of nasal catheters, frequently patients complain of irritation if the catheter is less than 4 inches long. On the other hand, if the nasal catheter is so long as to reach almost to the glottis, it may cause cough and irritation. I have used the happy medium, seeing that the catheter (not the urethral catheter, but a soft rubber tube F. 8 in diameter with 4 or 5 terminal perforations) is at least 4½ or 5 inches long, so that the oxygen flows into the pharynx, and thus irritation of the nasal mucosa, or of the glottis or lowermost part of the pharynx is avoided. In that way one can frequently administer as high as 8 liters of oxygen per minute, which readily insures concentrations of 50 per cent. I do not employ a wash bottle with the nasal catheter, as it is not the absence of moisture that is irritating.

DR. ALVAN L. BARACH, New York: We have had at the Presbyterian Hospital thirty-five cases carefully treated with oxygen over a long period of time. Some of these patients were observed in the hospital for periods of from one to five months and others for shorter periods. These were patients who have not regained compensation under ordinary routine methods. Patients with rheumatism of the heart respond to

oxygen poorly. When they do improve, taking them out of the oxygen room or the tent frequently results in a recurrence of decompensation. An entirely different effect is obtained in the treatment of patients with cardiac failure the result of a myocardial fibrotic or degenerative lesion and not of rheumatism. In these patients we have seen a restoration of compensation in from two to four weeks. This was attended by a significant rise in the carbon dioxide content of the arterial blood, sometimes as high as 20 or 30 volumes per cent. As the patient gets better and the pulmonary ventilation falls, the carbon dioxide content of the arterial blood will gradually be decreased toward the normal level. If we gradually take these patients out of the oxygen, we find that many of them maintain compensation for a year or longer. We have had patients who were unable to walk and who subsequent to oxygen treatment of three or four weeks were able to walk as far as two miles a day. I think that what Dr. Friedrich said is probably true. I have been impressed by the failure to have animals live in a concentration of oxygen of over 75 per cent. I spent several years trying to get animals gradually to endure concentrations of 80 per cent, keeping them at 50 per cent and then 60 per cent; but every time the concentration went over 75 per cent the animals developed pulmonary edema in two or three days and died. Sayers has shown that if animals are kept in oxygen sixteen hours out of twenty-four they may survive without developing that irritating pulmonary lesion. I think it is probably true that a great many of the cases that I have treated might have been better helped by the use of very high concentrations of oxygen for shorter periods.

DR. ROBERT L. LEVY, New York: One who is going to administer oxygen to patients with acute cardiac failure should not wait too long. The oxygen should be given in sufficient concentration to overcome anoxemia and long enough to enable the heart to recover from its acute functional disturbance.

HIGH FREQUENCY CURRENTS IN PERFORMING BIOPSIES

JACQUES P. GUEQUIERRE, M.D.

AND

FRED D. WEIDMAN, M.D.

PHILADELPHIA

Templeton¹ and others² have already indicated the value of high frequency currents in the treatment of various dermatoses requiring excision, and others have indicated the value of the so-called radio knife in such major procedures as amputation of the breast. The present communication, however, has nothing to do with such phases of the field. It is true that Templeton spoke of the usefulness of this modality in performing biopsies and exhibited several photographs. However, the attempt was not made in such presentations to distinguish between the value of the coagulating and cutting currents. It is to this particular phase that the present communication is confined.

It has been the experience of doubtless many pathologists to have specimens submitted for histologic examination which have been removed by the coagulating current and in which the severity of the coagulative processes has been sufficient to compromise or even destroy the value of the specimen for histologic examination. This has naturally prejudiced them against such a technic.

Accordingly, it came as a pleasant surprise to us to encounter certain specimens in which the zone of coagulation necrosis was extremely narrow and in no way interfered with histologic interpretations. In checking up for an explanation it was found that the cutting current rather than the coagulating current had been employed in such cases, and, except in cases in which we had purposely used the coagulating current to note its effect, its use was due to our failure to "throw the switch" to the cutting current. Consequently we have confined ourselves entirely to the employment of the cutting current for biopsy purposes and with such good results that we feel it advisable to emphasize the availability of this technic in the routine performance of biopsies. Our experience parallels that of Dr. F. H. Krusen,³ who has been using this method for some time.

We have already pointed out the difference between the therapeutic and the biopsy aspects of the situation and the fact that we are confining ourselves to the biopsy phase. In doing this it is appreciated that a certain conflict might arise; i. e., that by employing the cutting current in malignant conditions, the advantage of coagulative effects would be forfeited. We feel, however, that this disadvantage is only apparent and we overcome it by always coagulating or desiccating thoroughly the site of the excised lesion. With lesions so large that it would be inadvisable to excise them in toto with the cutting current, we excise only a small portion for histologic examination and then promptly follow up with the coagulative technic. We excise the smaller lesions in toto and retain the entire sample as a biopsy specimen. In this way any clash between the welfare of the patient (necessitating coagulating current) and an optimum histologic section (cutting current advisable) is avoided.

We feel particularly justified in calling attention to our experience, because the adoption of the cutting current technic will make for the performance of larger numbers of biopsies. Thus, the endotherm apparatus is standard equipment in practically every dermatologist's office and it needs but the turn of a switch to make the cutting current available. It is not necessary to call on the surgical tray except when bleeders are encountered. This makes for rapidity and simplicity.

Furthermore, there is a psychologic aspect. The inherent aversion of the patient to the use of the scalpel or other cold steel is overcome. The operation is bloodless and sutures are unnecessary. All these circumstances may play a part in forestalling misgivings on the part of a certain type of patient. The postoperative events are free of unpleasant memories, for both the physician and the patient. The base of the wound can be coagulated or desiccated immediately after the specimen is removed. It is sterile, heals nicely and does not leave a highly disfiguring scar. All these factors may be cited as advantages of the cutting current technic over ordinary surgical excision, and, when explained to the patient tactfully, will tend to secure his consent for the operation and permit the acquirement of a specimen that will be useful for histologic examination.

THE LIMITATIONS OF THE CUTTING CURRENT

The most serious limitation of the cutting current is muscular twitching; workers are in agreement that nothing has been discovered thus far which can prevent it. The sudden spasm interferes with the precise course

3. Krusen, F. H.: Personal communication to the authors.

From the Laboratory of Dermatological Research, University of Pennsylvania School of Medicine (Dr. Weidman).

Read before the Section on Dermatology and Syphilology at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 13, 1934.

1. Templeton, H. J.: *California & West. Med.* 30:83-87 (Feb.) 1929.

2. Ward, G. E.: Value of Electrothermic Methods in Treatment of Malignancy, *J. A. M. A.* 84:660 (Feb. 28) 1925. Hollander, Lester: *M. Rev. of Rev.* 34:203 (April) 1928.

of the needle and hence of the incision. As a result, the needle may be directed to some portion of the specimen which might be particularly useful in the histologic examination and which would therefore suffer an undesirable coagulation. A second disadvantage is encountered in extremely small lesions. In a trial on a guinea-pig as well as in operating on patients we have found that it is not advisable to attempt to secure a specimen less than 6 or 8 mm. in diameter. It might also be considered a disadvantage that a steady hand and reasonable cooperation on the part of the patient are necessary; these, however, are problems that would have to be met in the individual case.

Apparatus.—It is not likely that the instrument of one manufacturer will be found superior to that of another. Our own instrument is a Westinghouse Model F endotherm. Each operator will establish his own personal equation by trial and error as to the optimum "cutting intensity" and "current controls" to be employed. In our own instrument the best results were secured with the cutting intensity at E and the current control at 7. With this a sufficiently rapid excision was secured with a minimum of coagulation necrosis around the specimen. Incidentally, we found that the amount of necrosis was far less, indeed almost nil, at the bottom of the specimen; it was much greater along the line of primary incision which is commonly known as the line of circumvallation.

Technic.—This does not differ from that employed in ordinary therapeutic work. Procaine hydrochloride anesthesia is employed. The patient is made as comfortable as possible and the hand of the operator is steadied by appropriate means. The attempt should be made to circumvallate the lesion completely down to the subcutaneous tissues at one maneuver; i. e., to avoid if possible the necessity of retracing or supplementing the original incision. After circumvallation the lesion can be transfixed with an ordinary sewing needle, which is thereafter used as a tractor during the removal of the lesion from the parts underneath. After the removal of the specimen, a nonbleeding but somewhat moist base remains, which is then coagulated or desiccated and painted with an antiseptic such as gentian violet. Sutures are not employed.

SUMMARY AND CONCLUSIONS

The objections of the pathologist to the use of coagulating currents can be largely overcome by adhering to the cutting current. The method is not infallible, owing to such factors as muscular twitch, an unsteady hand, or an anatomic location such as the face, which limits the removal to a very small specimen. Barring these conditions the readiness of the apparatus, the bloodlessness, the insensitiveness to postoperative pain and the psychologic effect on the patient all contribute to the securing of a greater number of biopsies, which are so sorely needed for the advance of dermatology in general, to say nothing of the assistance that accrues in confirming the diagnosis.

1930 Chestnut Street.

ABSTRACT OF DISCUSSION

DR. GEORGE M. MACKEE, New York: Until the last few years I was unable to remove small pieces of tissue with the high frequency current without causing too much coagulation for satisfactory histologic study. Now, however, with better apparatus and improved technic, I find it possible to remove all

but very small pieces of tissue with the cutting current, with an amount of coagulation that does not preclude adequate microscopic examination. I am therefore in agreement with the authors. The apparatus must be modern, the controls carefully adjusted, and the excision performed quickly. The novice should first experiment on a piece of raw beef and then on animals. In my experience, surgical diathermy gives rise to a larger percentage of hyperplastic scars than do the scalpel, punch or scissors. As a rule, however, the hyperplasia usually disappears in time, at least to a large degree. A wound caused by the cutting current will not heal by primary intention, as a rule, unless the fine line of coagulation is removed before the wound is closed. Unless sutured, wounds caused by a biopsy punch are round and rather conspicuous. The question of a cicatrix is important in some instances. The principal reason for using the cutting current when performing a biopsy is that many believe that the coagulation prevents spreading or metastasis of malignant cells. It now appears to be the consensus among pathologists and among cancer experts that this danger has been overemphasized. It is claimed now that there is no danger, provided the instrument is sharp and the tissue is not massaged or squeezed.

DR. MAX S. WIEN, Chicago: I have been using the cutting current at the Cook County Hospital in the treatment of superficial malignant growths. I have also taken specimens of tissue for histologic study and with large specimens had no trouble with distortion as the result of the current. In the smaller specimens, however, which have been studied in collaboration with Dr. Jaffe at the hospital, there were noted changes that were akin to those produced by electric burns resulting from accidental or intentional electrocution. These consisted of dehydration and coagulation with increased basophilic staining and liquefaction of the connective tissue in the pars reticularis, and a stretching of the epithelial cells of the rete malpighii with strandlike proliferation into the cutis, forming whirls in some places. It was only in the smaller specimens that we noted such changes; otherwise we have found it a very satisfactory method for removing larger pieces of tissue for histologic study.

DR. FRED D. WEIDMAN, Philadelphia: No doubt every dermatologist has excised lesions as a therapeutic rather than diagnostic procedure and has turned them over to the laboratory in the hope that the pathologist may be able to salvage something out of the perhaps tattered and "cooked" specimen. As a result, the pathologist has rightly become prejudiced against coagulating modalities in securing biopsy samples, and it is the duty of the clinician to correct, if he can, these shortcomings, which waste the time of the pathologist and give no information to benefit the patient. I must confess that I prompted Dr. Guequierre to report this experience as part and parcel of a general propaganda in favor of more and better biopsies. As to the danger of biopsies in malignant conditions, I was influenced largely in favor of doing them by a paper that Francis Carter Wood read before the Philadelphia Pathological Society ten years ago. He used one series of cancer-bearing mice on which biopsies were done, another series in which nothing was done, and a third series in which he massaged the experimental tumors. He found at necropsy that there was not any increase of metastases in those in which biopsies had been done; in those in which the lesions had been massaged there was a marked increase. At the Philadelphia Oncologic Hospital we take biopsy specimens of every lesion as a routine procedure even when the clinical diagnosis is clear. We do this with the specific purpose of being able to check up later on those cases in which we get remarkable therapeutic results in what appeared to be perhaps hopeless cases, under these circumstances. The question always arises whether we were dealing with a malignant condition or only something that looked like it. Did we err in our clinical diagnosis? Then we always have the biopsy sample to go back to as a check. Furthermore, I can't say that we have had any evidence that the incidence of metastasis has been any greater as the result of our routine and therefore extensive biopsy procedures. As to the detailed cytologic changes which Dr. Wien brought up, those have been elaborated by Dr. Ellis of Chicago recently in the *Archives of Pathology*. They have not fallen in the field of our communication.

THE ASSOCIATION OF SINUS DISEASE
AND MIDDLE EAR INFECTION

M. M. CULLOM, M.D.

NASHVILLE, TENN.

The conclusions arrived at in this paper are based on more than one hundred cases of mastoiditis in private patients which I have observed since the influenza epidemic of 1918. A great many mastoid operations were performed in my clinic at the Vanderbilt Hospital. As I did not perform these operations it was not possible to get a thorough examination of the sinuses in connection with the mastoiditis, so those cases have not been taken into account. The case histories of these patients read so much like the histories of the patients that were carefully examined with respect to their sinuses, however, that it leaves no doubt in my mind that sinusitis was present in these cases to a very large per cent.

Following the epidemic of influenza in 1918 there were a great many cases of mastoiditis. There were also many cases of sinus infection. The association of sinus disease and middle ear infection did not make a definite impression on me until 1920. Then I had a run of mastoid operations in which I also did operations for drainage of the sinuses. At that time I had as assistant Dr. F. E. Hasty. I called his attention to the association of the two and we began to investigate their relation. The association was quite striking and I took to having a roentgenogram made of the sinuses in each case requiring one of the mastoid. We found that about 85 per cent of our mastoid cases also presented cloudy sinuses. We then discovered that there was in every case a cloudy sinus on the same side as the mastoiditis. There were any number of cases of middle ear infection which did not eventuate in a mastoid infection of sufficient severity to call for a roentgen examination which showed a cloudy antrum under transillumination on the same side as the middle ear infection.

In April 1925 I read a paper before the Tennessee State Medical Association on the subject of disease of the nasal accessory sinuses. This paper was written in 1924. In this paper I said:

While I have spoken of the various complications of sinus disease, I wish to emphasize one that has been brought home to me forcibly. I was somewhat surprised in reviewing our cases of acute mastoid abscess to find that practically all of our cases done during the last four years had empyema of one or more sinuses. There should be nothing surprising in the fact, however, when we consider that the pus draining into the postnasal space passes over the orifice of the eustachian tube. The surprising thing is that they do not all get infection of the ears.

In March 1926 I¹ reported a case and showed the patient before the Nashville Academy of Ophthalmology and Oto-Laryngology. I demonstrated a very cloudy right antrum by means of transillumination in the patient who had a discharging right ear. The case report was as follows:

A., a white man, aged 29, had not been feeling well the week of March 1. On Sunday, March 6, he had pain in the right ear. On Tuesday, the right ear began to discharge and the pain in the ear stopped. The patient continued to feel ill and the ear continued to discharge. He consulted me, Saturday,

March 13. The patient was pale and looked ill. There was a discharge from the right ear. After cleansing the ear, I found a small perforation in the drum membrane. There was a unilateral purulent discharge from the right nostril, causing excoriation of the skin. Transillumination showed the right antrum dark.

This case is reported to illustrate a group of cases that I have observed for the past six years; namely, middle ear abscess following empyema of the antrum on the same side as the ear involved. I would say, roughly, that 85 per cent of my mastoid cases coming to operation during the last six years have shown an infected antrum on the same side as the mastoid involved. There is nothing mysterious about this. The only thing surprising is that in all patients with antral empyema abscess of the middle ear does not develop, as the pus draining downward runs over the orifice of the eustachian tube, and the infection easily follows. It is the same mechanics that gives patients a middle ear abscess following irrigation of the nose.

In the fourteen years that have elapsed since I began to observe the association of sinus disease and middle ear infection, many observers have noted the association between infected sinuses and middle ear abscess. Unknown to me, Watson Williams had reported the same observations in a paper published in October 1924. In a study of forty-two consecutive cases of surgical mastoiditis he found the nasal sinuses infected in twenty-eight instances. In twenty-five of these cases the sinus infection was on the same side as the mastoiditis. As far as I know he has not followed up these studies.

In 1929 I read two papers on the etiology of middle ear suppuration, one before the Tennessee State Medical Association in April and one before the Southern Medical Association in November. I showed x-ray plates of the mastoids and the sinuses, demonstrating the association of mastoiditis and sinus suppuration on the same side. At the Philadelphia session of the American Medical Association I had an exhibit of x-ray plates in the Scientific Exhibit showing mastoiditis and sinus suppuration on the same side with the exception of one case, which showed a cloudy antrum on the right side and cloudy cells in the left mastoid.

Campbell's² paper in 1932 on the association of acute sinusitis and acute otitis media in infants and children is based on the study of 150 cases of otitis media in children between the ages of 2 days and 11 years. One hundred and ten of the children were under the age of 2 years. In 140 of the 150 cases a positive diagnosis of purulent sinusitis was made by means of the nasoscope. Of the remaining ten cases six were classified as doubtful because no pus could be seen, but the intranasal appearance indicated probable infection of the sinuses. Only four patients showed no evidence of sinus infection when examined by the nasoscope and in each of these cases a thick purulent secretion had been draining from the sinuses for long periods suggesting that the otitis was of the chronic type. In such cases the purulent sinusitis probably present at the start of the sinusitis had apparently cleared up. If the six doubtful but probable cases of sinusitis are classed with the positive ones, the percentage of cases in which acute sinusitis accompanied the otitis is 97.3. In twenty-five cases roentgenograms were made and in only one case in which there was nasoscopic evidence of sinusitis

¹ Read before the Section on Laryngology, Otology and Rhinology at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 15, 1934.

2. Campbell, E. H.: Association of Acute Sinusitis and Acute Otitis Media in Infants and in Children, *Arch. Otolaryng.* 16:829 (Dec.) 1932.

were the roentgen examinations negative. The patient, an infant of 3 months, showed a large amount of pus in both middle meatuses and both sphenoid-ethmoid recesses. Of eighty-five infants under 1 year of age with otitis media, definite infection of the sinuses was found in 97.5 per cent and probable infection in 100 per cent.

Dr. Campbell says:

While the total number of cases is small, it represents a consecutive unselected group and is therefore probably an accurate indication of the percentage of association of the two conditions. Therefore, it seems reasonable to conclude that when an aural discharge is present in an infant, sinusitis is also present. This should be of considerable significance to the pediatricians, who for the past few years have stressed the importance of infection of the ear as a factor in gastro-intestinal disturbance of infants but who have not taken into consideration the coexisting sinus infection. If, as they assume, infection of the ears have such a deleterious influence on the infant, how much greater effect would the infected sinuses have, which produce perhaps twice as much pus as do the ears. It seems to me that infected sinuses are of more importance than infected ears in gastro-intestinal conditions, and that it would be as rational for the pediatrician to advocate operative treatment for such conditions of the sinuses as to insist that mastoidectomy be performed.

This is directly in line with an observation I made in two papers read in 1929 before the State Medical Association of Tennessee and the Southern Medical Association. In these papers I said:

Many observers have noted gastro-intestinal disturbance in infants as a result of an obscure infection in the mastoid. The clinical course of these cases was athrepsia, vomiting, diarrhea, final cachexia and death. Autopsy disclosed in all of them a purulent infection of one or both mastoids. Floyd of the University of Iowa and Alden and Lyman of Washington University have made a practice of opening the mastoid of these cases, and report good results if done early. Since I have noticed the intimate connection between purulent sinus infection and mastoiditis, I have wondered if there were not a previous sinus infection in these cases from which the mastoid became infected. It would be interesting if all the children showing this syndrome could have an x-ray of the sinuses.

I am deeply grateful to Dr. Campbell for carrying out this exhaustive study of the association of acute sinusitis and acute otitis media in infants and children. In a measure it establishes the truth of the observation I made seven years ago. The facts he established are of supreme importance and should have a direct bearing on the question of prognosis and treatment of acute otitis media.

Fowler³ approached the subject from a different angle. The study is based on the examination of 100 children (200 ears). There were five cases of nonsuppurative otitis media, thirty-seven of healed suppurative otitis media, thirty-four of recurrent suppurative otitis media, thirteen of chronic suppurative otitis media and eleven of nerve deafness. The study was extremely thorough. The diagnosis was made not alone from the immediate pathologic conditions presented but also from the whole history of the case. The roentgen examinations were interpreted by Dr. Frederic M. Law, without knowledge of the clinical diagnosis. The youngest patient was 3 years of age, the oldest was 19, and the average of the group was 11.

There was a history of discharge or pain in 78 per cent of the cases, of exanthems in 65 per cent, and of colds, influenza or pneumonia in 66 per cent. There

were seven mastoid operations. In the five cases of chronic nonsuppurative otitis media all presented histories of repeated colds, and 60 per cent a history of earache. It is probable that all the patients had suffered from infection of the ear.

The roentgen examination showed that the sinuses were involved in 86 per cent of the cases. This is interesting, as my observations reported in 1926 showed that 85 per cent of my mastoid cases showed involvement of the sinuses by roentgen examination. If the other 15 per cent could have been examined at the inception of the suppuration I have the feeling that practically 100 per cent involvement of the sinuses would have been found.

To my mind this study of Dr. Fowler's constitutes one of the most important contributions that has been made to the study of deafness. Since 1920 I have had the growing conviction that nearly all forms of deafness are the result of infection and that the infection for the most part is by continuity and not blood borne.

There are many who can remember when Dr. Shambaugh first raised his voice against the orthodox pronouncement that deflection of the nasal septum causes deafness. I think he is now coming into his own and that the newer pathology will place the blame where it belongs, on infection. Not that I deprecate the operation of submucous resection. Deflection of the septum is a grave offender by reason of blocking the drainage from the sinuses and thereby setting up a condition which may result in purulent middle ear infection and mastoiditis but also thickening of the mucous membrane and resulting deafness even if no diagnosis of purulent infection can be made. How often has the surgeon removed a deformed nasal septum to find behind it an active ethmoiditis or a blocked antral orifice?

Since observing the association of sinus infection with middle ear infection I have examined my hard-of-hearing patients for associated sinus infection, which has been found in a very large percentage of cases. Two cases are reported that were of especial interest to me.

H. H. C., a boy, aged 9 years, was brought to me suffering with an acute infection in his left maxillary sinus in July 1919. I treated him until the acute symptoms subsided. In 1929 he returned on account of deafness in his left ear. His left ear drum membrane was thickened dull in appearance with absence of light reflex. Bone conduction was better than air conduction, Weber lateralized to the left, a watch could be heard at 8 inches. Transillumination showed a cloudy left antrum. A roentgenogram made by Dr. Shoulders showed the left antrum to be very cloudy. All other sinuses were clear. He had been away at school most of the time since I had treated him in 1919. He had had treatments for sinus disease numerous times while he was away.

In 1929 I was consulted by his mother, who had noticed for some time that she was gradually losing her hearing. The drum membranes of both ears were dull with very little light reflex. Bone conduction was better than air conduction. Weber not lateralized. A watch could be heard at 4 inches in both ears. Transillumination indicated cloudiness of both antrums. Dr. Shoulders reported from roentgen examination that both antrums were cloudy, indicating a chronic thickening of the membranes.

These two cases furnish food for thought. May they not furnish a probable explanation for much hereditary deafness? If the son had been deaf in both ears it might not have made such an impression. But I was able to show from my records that the son suffered with unilateral sinus disease in his ninth year. He returned in ten years with a well developed chronic

3. Fowler, E. P.: The Incidence of Nasal Sinusitis with Diseases of the Ear, Arch. Otolaryng. 9: 159 (Feb.) 1929.

antrum infection on the same side and a well developed chronic otitis media catarrhalis on the same side, while the maxillary sinus and the ear on the other side were normal. Every one knows how frequently sinus disease is found in families and I have the strong feeling that it is the tendency to sinus disease that is inherited rather than familial deafness.

Fig. 1.—At left, densely cloudy left antrum, at right, cells of the left mastoid broken down, in the case of J. C., a boy, aged 16, with discharging ear four months following a cold.

In "Etiology of Middle Ear Suppuration," Southern Medical Association, November 1929, I listed among the causes the great prominence given by most authors to specific infections in the exanthematous diseases, scarlet fever, measles, diphtheria and epidemic influenza. I made the following commentary:

The cases of infectious diseases attended by middle ear abscess would, I believe, show a very large percentage of existing purulent infection in some one of the accessory sinuses if they were properly examined. The swimming pool and the nasal douche cases are strictly analogous to infection from infected sinuses. Purulent material from the patient's own nose is washed into the eustachian tube or else water infected with virulent bacteria gives entrance through the nose.

The views expressed in these words based on my observations covering a nine year period have since received abundant confirmation in the work of others.

Childs⁴ submits a study of 383 cases of scarlet fever admitted to the City Hospital and examined there by each department participating in the study. Roentgenograms were made during the first week of the disease. A group of these were reexamined at a later date at about the twenty-eighth day of the disease. Roentgen examinations were carefully made in the chin, nose, forehead and lateral positions. No attempt was made to take the sphenoids. They were classified as clear, hazed and dense, and opaque. These studies were begun in February 1930 and still continue.

Hoople and Cave⁵ presented a study of the same group of cases.

In only 9 per cent were the sinuses found clear. In other words, 91 per cent of the 383 cases showed sinus involvement by roentgen examination, 79 per cent showed hazing and density while 12 per cent were classed as opaque. The frontals were clear in 110 cases. In 30 per cent, or 123 cases, there was bilateral hazing of the maxillaries and ethmoids. There were 104 cases of bilateral hazing of the maxillaries, or 27 per cent. Pansinusitis was present in nine cases. There was maxillary involvement in well over two thirds of the cases. Ninety cases were restudied and only 12

per cent showed improvement. Thirty-six per cent showed no improvement and in more than 50 per cent there was definite evidence of the progression or extension of the sinus involvement.

There were no clear sinuses in the 3 and 4 year old group. From 5 to 14 the sinuses were clear in 8 per cent, while from 14 years on the proportion was from 11 to 14 per cent clear. The conclusion drawn by Baulmen, quoted by Silverman, is that the younger the child the more likely is sinus involvement. Thirty-three patients developed mastoiditis, shown by roentgen evidence and confirmed by surgery. In every case of mastoiditis there was roentgenographic evidence of sinusitis on the same side as the mastoiditis. A most significant statement to my mind is that in no case of clear sinuses did mastoiditis develop. This is strong presumptive evidence that middle ear suppuration comes from infected sinuses and that adenoids and tonsils play a very little rôle in its inception, though they may be a factor in its continuance. In the four groups of cases that are reviewed in this paper there are four separate angles of approach.

My group of considerably more than 100 cases dealt mainly with adults. Dr. Campbell's group of 150 cases dealt with infants. Dr. Fowler made a study of deafness in children which demonstrated 91 per cent of associated sinus disease. Dr. Hoople's series dealt with a very large number of scarlet fever cases in young children. The percentage of sinus disease present in his cases was about 91. Dr. Campbell found more than 90 per cent associated sinus disease while my mastoid cases showed about 85 per cent associated sinus disease. It would appear from these figures that the percentage holds about equally for all ages.

Now I shall pause and take stock of the case I have made out against sinus disease. As long ago as 1920 I began to suspect sinus infection as the guilty cause of middle ear infection and mastoiditis. A close follow up of mastoid and middle ear infection in more than 100 private cases of mastoiditis and a great many more cases of middle ear abscess that did not eventuate in surgical mastoiditis showed a demonstrable sinus infection in 85 per cent of the cases. Many ear men have

Fig. 2.—At left, both maxillary sinuses cloudy, at right, involvement of left mastoid cells, in case of M. H., a boy, aged 16, both of whose ears had been discharging for some time. Lately there had been pain in the left mastoid region. The left mastoid was operated on. The maxillary sinuses were drained a year later, after which the chronic purulent discharge from the right ear ceased.

communicated to me that investigation of their cases since I called attention to the condition has confirmed my observations.

1. The significant feature of these investigations is the fact that sinus infection was found on the same side as the mastoid in nearly all cases.

4. Childs, D. S.: New York State J. Med. 33:141 (Feb. 1) 1933.
5. Hoople, G. D., and Cave, L. S.: Otorhinologic Aspects of Scarlet Fever, J. A. M. A. 101:1121 (Oct. 7) 1933.

2. Dr. Fowler found in his large group of children suffering from deafness that 91 per cent showed conclusive evidence of sinus disease.

3. Dr. Campbell found conclusive evidence of sinus disease in 91 per cent of 150 infants suffering from middle ear abscess.

Fig. 3—Sinus infection followed by mastoid infection on the same side; acute mastoid disease on right side with active symptoms; acute infection of all sinuses not recognized clinically. Reproduced from a roentgenogram sent by Dr. Willis F. Manges, head of the department of roentgenology at Jefferson Medical College, Philadelphia. Dr. Manges sent roentgenograms of three cases showing the association of purulent sinus disease with mastoid infection; the other two are not reproduced here, as this illustrates the type of disease.

4. Dr. Childs and Dr. Hoople examined 383 cases of scarlet fever and found the sinuses involved in 91 per cent of the cases.

5. To go outside the scope of the charges brought against the defendant sinuses in the title of this paper I think it is competent and material to introduce other evidence proved against said sinuses. I had an exhibit in the Scientific Section at the Philadelphia session of the American Medical Association in 1931 showing a large number of x-ray plates demonstrating the association of sinusitis and nonspecific infections of the chest. Many of these patients were under treatment for supposed tuberculous infection. This exhibit was confirmatory of the work of Mullen, Manges, Jackson and others.

6. While the connection between sinusitis and retrobulbar neuritis is not on such a sound basis, the work of Leon White and others, as shown by Gordon Hoople, cannot be ignored. The weight of evidence is against the sinuses here, and further investigation will doubtless confirm their guilt.

7. It has long been believed that sinus disease is an etiologic factor in pneumonia, from the high percentage of infected sinuses found post mortem in patients dead of pneumonia. I feel that a case has been made out against infected sinuses that is truly appalling. The infected sinus is taking up a campaign against other bodily structures which is disabling, crippling and death-dealing. It has been the fashion lately to decry the sinuses as an important focus of infection. In the light of the evidence I think it is the real factor in focal infection. I have the feeling that, owing to the position of the sinuses at the top of the upper respiratory tract, they are a menace to all lower lying structures. The drainage from infected sinuses flows down over the postnasal opening of the eustachian tubes and brings about infection of the middle ear. The drainage flows over the adenoid tissue and may be the factor in adenoid infection. It flows down over the faucial tonsils and may account for infected tonsils. The drainage

follows the airway into the larynx and trachea and may set up pneumonia, bronchitis and nonspecific infections of the chest. The pus is swallowed in large quantities in severe cases and may set up digestive disturbances and interfere seriously with nutrition. It may be a potent factor in heart, kidney and joint disease.

The body may well be likened to a fortress or citadel. This fortress is beleaguered round about with billions of attacking forces seeking to gain entrance for the purpose of overwhelming and destroying it. The body, like a well designed fortress, is very well planned for defense. The skin may be described as the walls. The only way the invading host can effect an entrance through the walls is by means of a breach that comes about through traumatism. Like a fortress, the body has openings for the ingress of supplies and the excretion of waste.

If the enemy is debarred from effecting an entrance through the walls, where then is his best chance to gain admittance? Manifestly through the openings. What is the chance to effect an entrance through the openings designed for the excretion of waste? Not so good, as here the enemy would have to go against the current. Then evidently his main chance to get inside the defenses is through the openings designed for the reception of supplies. The enemy then seeks an opportunity to ride in on the food we eat, the water we drink, the air we breathe. Once having gained admittance, what does the enemy do? Having ridden in on the wings of contagion or infection through the air, or by means of infected food or water, he finds lodgment in a sinus, a tooth or a lymphoid structure. Having secured a footing he digs himself in and with that location as a base he multiplies and sends out attacking forces to find lodgment in other parts of the body, there to wield his destructive warfare until he is stamped out or until he permanently impairs or destroys the fortress.

It is evident that the great majority of bodily infections have their beginning in the upper respiratory tract. To you as ear, nose and throat men, what does this fact convey? To you is entrusted the front line of defense. You are the shock troops whose duty it is to meet the first furious onslaught of the enemy and stop him in his tracks. To you is given the organization of the clean-up squads that mop up the shell holes

Fig. 4—At left, densely cloudy right maxillary sinus, at right, cloudiness of left mastoid cells, in case of Miss E. J., aged 28, who had influenza. The left ear drum had been incised, after several days of suffering, one week before these roentgenograms were made. This is the only case of the author in which the infected sinus was on the opposite side from the infected mastoid. This mastoid cleared up without operation.

and underground hiding places of the enemy. You are hunting in big game country and you are on the trail of a quarry that is both cunning and dangerous. For thirty-eight years I have followed his trail, witnessed his depredations, and learned something of his habits,

his method of attack and his means of defense. He is now brought into the open more than ever before. It is our business to meet and destroy him. I do not share the fashionable pessimism of the present day in regard to the sinus problem. The surgical problems of the sinus are not different from surgical principles applied

for drainage. Hence it appears that sinus disease is a penalty man pays for assuming the upright position, thus radically changing the design of the Creator.

ABSTRACT OF DISCUSSION

DR. LYMAN G. RICHARDS, Boston: Dr. Cullom has presented figures and clinical data which tend to establish beyond doubt that there is a frequent coincidence and to a certain extent, at least, an etiologic relationship between sinus disease and middle ear infection. In many respects this is what one would expect, in view of the histologic anatomy of the nose and nasopharynx. Both the mucous membrane lining the nasal sinus and that lining the middle ear are parts of the same generic structure and have a right to be involved in the same inflammatory process. The earlier in life that this inflammation occurs, the more likely is one to find involvement of both structures, as shown by Campbell's figures, since in the infant the wider eustachian tube and the larger sinus ostium result in a freer communication between the sinuses and the middle ear. As age advances and the more complicated anatomic developments take place there occurs a change in this relationship, such that there is a greater likelihood that sinus infections may develop without necessarily involving the now better protected middle ear cavity. Even so, in such generalized involvements of the upper respiratory tract as are seen in scarlet fever, there are noted, as confirmed by Hoople's figures, frequent involvements of the nasal sinuses and a concomitant middle ear inflammation. As further statistical reports appear, one wonders how far this indictment of the nasal sinuses is to extend. What, for instance, would an investigation of the sinuses in cases of measles or whooping cough, perhaps even of chickenpox, show as to sinus involvement, at least as evidenced by the x-rays? Does it not seem probable that any of the epidemic diseases involving the upper respiratory tract will show a high percentage of sinusitis? The important question seems to be whether such involvement is of such clinical significance as to require specific treatment. This decision cannot be based entirely on the roentgen examination, and yet it must be admitted that this diagnostic feature is the one most commonly used to establish the existence or nonexistence of a sinus involvement. Unless further procedures, such as the examination of the sinus contents, bacteriologic and serologic, are brought into play, the diagnosis is only an assumption, and even then the actual infection may be in the submucosal tissues, where its presence can be proved only by microscopic examina-

Fig. 5.—Cloudy right antrum, cells of right mastoid very cloudy, and very large mastoid filled with pus, in J. E. F., a boy, aged 11. This case was very interesting, as the author predicted the outcome. The mother telephoned that the boy was in bed with influenza and was having a bloody discharge from the right nostril. The author told her that in a few days an abscess would probably develop in the right ear, which might go on to a mastoiditis. In five days he was brought to the office with an abscess in the right ear, which was incised under gas anesthesia. A profuse bloody discharge ensued for ten days and the mastoid became involved and went on to operation.

to other parts of the body. It is when we neglect simple surgical principles that we go wrong. In dealing with the sinuses we have a problem worthy of our best skill and I am optimist enough to believe that the ear, nose and throat profession will solve it.

CONCLUSIONS

1. One thing stands out with startling distinctness in these studies and that is how intimately infection in the middle ear is bound up with infection in the paranasal sinuses.

2. When one considers the fact that four different types of investigation show from 85 to 95 per cent of sinus involvement in middle ear infections, the magnitude and importance of the sinus problem becomes apparent.

3. Careful investigation shows sinus involvement in 91 per cent of a large number of cases of scarlet fever. The inference may be drawn that the other exanthematous diseases and epidemic influenza have also a high incidence of sinus involvement. From this it can be seen that a large percentage of the population have sinus involvement at one time or another. This means that a large proportion of the population are menaced by infection that may result in deafness, disease and death.

4. Sinus disease appears to be largely confined to human beings. Other animals appear to be practically immune to sinus infection and its crippling sequelae. When our ancestors walked on "all fours" the openings in maxillary sinuses were at the bottom or most dependent portion, thereby being in the most favorable position for drainage, as was also the opening in the sphenoid sinus. When man began to walk in the upright position the openings in the antrums were thrown to the top, or in the most unfavorable position

Fig. 6.—E. T., a youth, aged 17, had diphtheria at the age of 3 years. Since then there had been a chronic purulent discharge from the right ear. There was a large perforation of the drum. The color was very bad. Roentgen examination by Dr. Shoulders showed a very cloudy right antrum, right ethmoid, right sphenoid and right frontal sinus. The patient has a leaky heart.

tion of the lining membrane. Noninfectious allergic swelling of the sinus mucosa is well known to give roentgenographic evidence of varying degrees of opacity, which it is all too easy to ascribe to infection.

DR. GORDON D. HOOPLE, Syracuse, N. Y.: If Dr. Cullom's contentions are true, or if they are but partly true, prophylaxis

should play an important part in the prevention of ear abscesses and surgical mastoids. About one half of the total number of cases of scarlet fever in Syracuse are hospitalized. It would seem that an equal number of surgical mastoids should develop in the hospital cases and outside the hospital. It would seem that more would develop in the hospital, as the more seriously ill are the ones who are hospitalized. Looking at the records, however, I found that, of the last seventy-one mastoidectomies done on patients with infectious diseases at the City Hospital, more than 70 per cent of the total had been on patients brought into the hospital after the ear infection had started. In many of these cases the nasal hygiene had been haphazard during the early part of the illness. This is suggestive evidence that proper care of the nose in head infections is important and, if observed, will cut down the incidence of otitis media and mastoiditis. We should pass this information on to the internist, and especially to the pediatrician. We must seek opportunities to emphasize the importance of pain in the ear, of colds and sinusitis in children, and bring out the fact that deafness in later life is often the result of neglect in these conditions.

DR. GEORGE E. SHAMBAUGH JR., Chicago: The author's observation of the frequent association of sinus disease and middle ear infection is interesting and significant. In many patients the otitis media follows the sinus infection, and here the sinus can be blamed, but in others it must be said that the two processes have begun simultaneously from an acute head cold rather than the one causing the other. The relation of purulent sinusitis to deafness is of particular interest, and here one must examine further the author's statement that "nearly all forms of deafness are the result of infection and that the infection is by continuity and not blood borne." Mild and moderate degrees of deafness in childhood are practically always due to a middle ear catarrhal or infectious process. As high as 10 per cent of all school children suffer from this type of deafness at one time or another, but in the majority of cases the hearing returns to normal at puberty when the adenoid tissue in the nasopharynx shrinks up. Purulent sinusitis is undoubtedly a very important factor in deafness in children, as Dr. Fowler's studies have shown. However, when deafness in adult life is considered, an entirely different picture is seen. Most of the mild and moderate cases of tubotympanic deafness have cleared up and have left scarred and thickened drum membranes, but essentially normal hearing. To be sure, there are a number of adults with mild deafness that is the result of childhood tubal catarrh. This type of deafness usually is not progressive, since the etiologic factor, the hyperplasia of lymphoid tissue in the nasopharynx, disappeared at puberty. The most important cause of progressive deafness in adult life is, unfortunately, otosclerosis, which accounts in my statistics for approximately 70 per cent of severe adult deafness. Since 18 per cent of adult deafness is due to a primary nerve defect, either congenital, acquired from an acute infection, acquired from a chronic focus of infection, or occupational, it is seen that in adult life the majority of severe deafness is not due to direct extension of infection from the nasopharynx; in fact, I have found suppurative sinusitis in very few severely deafened adults.

DR. S. S. EVANS, Memphis, Tenn.: The close association of the mastoid and middle ear with the nose and accessory sinuses would lead one to think that mastoid infections may as well be coincidental. It has often been suggested that the mastoid may be considered anatomically another nasal accessory sinus. I do not recall having seen an otitis media or mastoiditis following maxillary sinus infection of dental origin; therefore I have reason to believe that otitis media and mastoiditis depend more on the virulence of the organism and resistance of the host than on a primary sinusitis. It has been my observation that the otitis media often begins at the first stage of the infection at the same time the sinus infection begins. This is during the so-called stage of congestion and before there is much drainage. A bacteriologic and cytologic examination of the aural and sinus discharge along with a more careful history of the time of onset of fullness or pain experienced both in the ear and over the maxillary sinus area would be of interest. Whether the mastoiditis is secondary or coin-

cidental, there remains the fact that both should be treated. One is prone to direct attention to the mastoid infection and neglect a sinusitis. A careful study of the sinuses should be made as a routine in all cases of middle ear disease.

DR. J. A. PRATT, Minneapolis: I believe that most of the infection when there is sinus involvement is due to mechanics rather than to continuity of inflammation. With the postnasal space filled with discharge, by sneezing, coughing and blowing the nose one forces the infected matter into the middle ear. If more children hawked back instead of blowing the nose to clean it, there would be about 50 per cent less deafness. Then, in blowing the nose, nearly every one holds one nostril and then the other, and, of course, if one side is blocked and the pharynx is filled with discharge and one closes the open nostril and blows, one is liable to inject the discharge into the middle ear. In Minneapolis, where there are so many lakes, mastoid cases appear during the dog days, because the children dive and come up and blow the nose. There will be a blockage, they will blow it into the ear, and in two or three days there will be a discharge from the ear. I have seen it after twenty-four hours, a suppurating, breaking drum. If people are taught to clean the nose by hawking back, or, if they do blow, to do it with both nostrils open, a great many of these cases will be relieved and improved, and this infection will not develop.

DR. M. M. CULLOM, Nashville, Tenn.: Dr. W. F. Manges, head of the department of roentgenology of Jefferson Medical College, makes it a practice to roentgenograph the sinuses of every mastoid patient he is asked to examine. In three cases that came to him the same day, sinusitis had not been suspected. He made roentgenograms on his own account and found sinus involvement in all three. He writes, "I am in entire agreement with you as to the causal relation between sinusitis and middle ear infection." It has been my experience that the symptoms of the cold come first and later on the development of the infection in the middle ear. I think that the infection in the sinuses is the cause of the infection in the ear.

Clinical Notes, Suggestions and New Instruments

SMALL SPINDLE CELL SARCOMA OF THE KIDNEY IN THE ADULT

E. A. WATSON, M.D., GRAND ISLAND, NEB., AND
B. CARL RUSSUM, M.D., OMAHA

The rarity of spindle cell sarcoma of the kidney in the adult is indicated by the fact that Otto Lubarsch in 94,498 autopsies found twenty sarcomas of the kidney, only four of which were classified as spindle cell sarcoma. In the same series he encountered 201 carcinomas. At the pathologic institute of the University of Berlin from 1898 to 1922 there were found thirteen sarcomas in 30,820 autopsies. The rarity of the condition prompted Kretschmer and Randolph¹ in 1928 to record a single case encountered at the Presbyterian Hospital in Chicago. Hyman² observed only two sarcomas in ninety-nine renal neoplasms.

REPORT OF CASE

P. J. C., a white man, aged 45, the manager of a lumber company in a small town in Nebraska, presented himself for examination, Nov. 14, 1933, with the following history: His mother died at the age of 60, of an unknown cause. The father died at 54 of pneumonia. There were four brothers and four sisters living and none dead. The siblings were all in good health. The patient had had no disease of importance in the past. In 1916 a gastro-enterostomy was done for duodenal ulcer with satisfactory results.

The patient smoked, and drank three cups of coffee daily, a considerable amount of beer and some hard liquor. His strength was poor; he worried considerably. He tired easily

1. Kretschmer, H. L., and Randolph, H. S.: Spindle Cell Sarcoma of Kidney in Adults, *Ann. Surg.* 88: 1033-1038 (Dec.) 1928.
2. Hyman, Abraham: Observations on a Series of Ninety-Nine Renal Neoplasms, *Am. J. Surg.* 5: 102-127 (Aug.) 1928.

and slept well. His weight was 130 pounds (59 Kg.) and he felt that he had not lost much.

He complained chiefly of some headache, pain in the lumbar region which was not bad, and at times distention which was not severe. The appetite was poor; he belched some gas and at times was nauseated. There was some pain immediately after eating. The bowels were constipated and the patient had to take some kind of a laxative. There was no genito-urinary history such as burning or difficult urination, and the patient had noticed no cloudiness of the urine. He said that he had always had some gastric disturbance but was relieved of most of this after the stomach operation. In the past month there had been considerably more pain localized to the right lower quadrant of the abdomen, quite severe at times, and there was always some pain present. There was also pain in the back with weakness and tiredness, and increased nervousness. There was no increase of pain at night. His color was good and he was fairly well nourished. The skin was smooth and moist.

The eyes reacted to light and in accommodation. The teeth were all false. The heart was normal in size and there were no lesions. The chest was well filled. Excursion was good, with nothing abnormal found. The abdomen was flat and tender over the entire right quadrant, more marked in the lower region of McBurney's point. There was slight tenderness in the back over the kidney as well as a more marked tenderness in front. Neurologically the examination was negative.

The blood pressure was 120 systolic, 85 diastolic. The blood count showed: red blood cells, 4,640,000; white blood cells, 8,300; hemoglobin, 74 per cent (Dare).

Fig. 1.—Appearance of kidney.

The specific gravity of the urine was 1.012. The urine was acid and contained no albumin or sugar, casts or kidney epithelium. There was a trace of diacetic acid. The urine was about one plus positive for pus cells and a later specimen showed from two to three plus pus cells.

Because of the combined observations a Cole-Graham test was made of the gallbladder and a gastro-intestinal series of roentgenograms was made, which disclosed a poorly concentrating gallbladder, a working gastro-entrostomy and later a visualized and segmented appendix with tenderness over it, the greater tenderness being over the cecum.

November 22, because of the combined symptomatology and physical examination and carrying out the wishes of the patient, the appendix was removed. At this time the right kidney was explored and found enlarged to about one fourth of the normal size and smooth, and no defined mass could be felt. During the first four days of convalescence the patient was free from pain and very optimistic. From this period on he complained of pain in the entire right quadrant, which seemed to increase each day.

December 5, a diodrast injection was done and the following observations were recorded: No stone shadows were seen on the preliminary picture. A definite hydronephrosis of the right kidney with marked clubbing of the upper and middle calices was found. The lower calix was not filled in any of the pictures. The opening of the pelvis into the ureter was very sharp, as if contracted by a stricture or outside pressure. There was also a loculation of the right ureter just as it entered the bladder. The pelvis of the left kidney appeared normal. There was a slight dilatation of the lower end of the left ureter.

The diagnosis was hydronephrosis of the right kidney.

December 6 the patient was taken to the operating room and a ureteral dilator was passed on the right side. Following this, there was some amelioration of symptoms and on December 9 he was discharged from the hospital with instructions to return for observation.

Immediately after his discharge and on reaching home the pain became very severe and he returned to the hospital. December 20, a renal function test was done and the left kidney

Fig. 2.—Section of kidney tumor under low power.

was found to be doing all the work. We still hesitated to operate, but the pain was severe, and at this time a mass could be palpated in the right kidney region, so an operation was deemed advisable, and on December 26 a nephrectomy was done. The lower pole was found adherent to the peritoneum with two small abscesses between, where an evident explosion of the lower pole of the kidney had occurred. This mass had evidently taken its origin in the cortex and had broken through the

Fig. 3.—Section of kidney tumor under high power.

cortex with ectropion of the tissue like a full bloom rose. Photographs and measurements of the mass were taken after several days in a hardening solution, but they are fairly descriptive of the condition (fig. 1). The tumor mass measured, after hardening, 12 by 12.5 cm.

Pathologic examination of the kidney and the upper 1.5 cm. of the ureter revealed that the kidney was 12.5 cm. long and up to 7.5 cm. wide in its lower half and 8.5 cm. from front to back. It had been opened. The lower three fourths of the

kidney substance was replaced by a tumor mass, which was gray, mottled with yellow, nodular and bulged beneath the surface of the kidney. It compressed but did not invade or arise from the kidney pelvis.

Microscopic examination revealed a diffusely growing cellular tissue in which were embedded occasional glomeruli and kidney tubules. The cells making up the section were polygonal and spindle cells growing diffusely. There were many mitotic figures, and many areas contained numerous polymorphonuclear leukocytes. In a few places there were thin-walled blood vessels forming a skeleton for the tumor cells. There was none of the extreme lipid deposit usually seen in a hypernephroma, and there was no tubular arrangement or papillary formation sometimes seen in carcinoma of the kidney. In the margin of the growth there was a fibrous thickening, apparently the kidney capsule.

The diagnosis was spindle cell sarcoma of the kidney.

This growth was evidently very rapid. We are confident that the majority of the growth and bursting of the kidney occurred between the operation of November 22 and the one of December 26.

May 1, 1934, the patient died at his home some distance from me. Our last examination was on Feb. 8, 1934. The patient was failing very rapidly and a mass the size of a grapefruit could be felt in the right lumbar and kidney region. We were informed that this mass had grown to fill the entire right quadrant of the abdomen. We are of the opinion that, at the time of death, metastasis of the lungs could also have been demonstrated.

MEDIASTINAL AND INTRASPINAL PERINEURIAL FIBROBLASTOMA (HOUR-GLASS OR DUMB-BELL TUMOR) REMOVED BY ONE-STAGE OPERATION

STUART W. HARRINGTON, M.D., and WINCHELL MCK. CRAIG, M.D.,
ROCHESTER, MINN.

Many hour-glass or dumb-bell tumors have been reported in the literature, and they occur with relative frequency in the cervical, thoracic and lumbar spine. Those in the cervical and lumbar regions do not present the same surgical problem as do those in the thoracic region. The reason for this is that the extraspinal portion of the tumor in the thoracic region is in the mediastinum and encroaches on the adjacent intrathoracic structures. This involves the double surgical problem of combining the procedures for an intraspinal and an intrathoracic tumor. In a careful review of the literature, we have been unable to find the record of any case in which this type of tumor has been removed successfully in one stage. In the majority of cases the intraspinal portion is removed first, the intrathoracic portion being reserved for removal at a second stage. The procedures may be reversed, depending on the predominance of symptoms. Our reason for doing the operation in one stage was that, in our previous experience with the two-stage operation for the removal of similar tumors, complications followed that we thought could be avoided by removing the tumor in one stage.

REPORT OF CASE

A married woman, aged 34, consulted her physician because of occasional subjective sensations of weakness in the knees. This had been present to a mild degree since the birth of her child four years previously. During the past year these intermittent attacks had progressed to the point at which she felt definitely unstable on her feet, and in addition she recently had subjective numbness of the toes of both feet. Her examination at that time was essentially negative except for the roentgenogram of the thorax, which depicted a shadow in the left thoracic cavity, and in the lateral views the shadow was attributable to a mass in the left posterior mediastinum. It was suspected that the mediastinal tumor might be contributing to her symptoms and she was referred to us for further consideration.

This case was of clinical interest because the early neurologic symptoms were mild, indefinite and associated with generalized symptoms of chronic nervous exhaustion. It illustrates the importance of a thorough general examination of patients with this type of complaint, for during the course of her general examination the roentgenogram of her thorax was taken and the lesion found in the posterior mediastinum. It is unlikely that the mediastinal portion of this tumor contributed to her symptoms, as benign tumors in this region rarely produce symptoms until they have reached considerable size, thereby causing pressure on the surrounding mediastinal structures. Among the patient's general complaints there were definite symptoms of weakness of the legs as well as numbness of the feet, which indicated that the mediastinal tumor might be of the dumb-bell type and that the neurologic symptoms might be due to mild pressure on the cord. By the time the patient had reported to the clinic for examination, her symptoms had progressed to the point at which definite signs of compression of the spinal cord could be elicited.

The general examination was essentially negative except for the roentgenologic examination of the thorax, which disclosed a circumscribed shadow of soft tissue at the left of the fifth and sixth ribs on the left side, posteriorly (fig. 1). A localized roentgenogram of the spine revealed erosion of the left pedicle of the fifth dorsal vertebra and upper border of the left pedicle of the sixth dorsal vertebra. The tumor was extruding through the intervertebral foramen between the fifth and sixth dorsal spines and into the mediastinum. The intervertebral foramen was eroded and enlarged by the extruding tumor. There was increase in width of the fifth intercostal space and erosion of the posterior inferior border of the fifth rib and posterior superior border of the sixth rib. A roentgenologic diagnosis of neurofibroma of dumb-bell type, invading both spine and mediastinum, was made.

Neurologic examination revealed a loss of epigastric, mid-abdominal and hypogastric reflexes, with diminution of the patellar and achilles reflexes on both sides. The gait was spastic and there was a slight area of anesthesia on the plantar surface of both feet. Spinal puncture was made, and the cerebrospinal fluid was found to contain 40 mg. of total protein, with a positive globulin reaction. There was no pleocytosis. A complete subarachnoid block was present, as demonstrated by the lack of response in the manometer when the jugular veins were compressed. The areflexia, subjective numbness and anesthesia, as well as the complete subarachnoid block, were indicative of compression of the spinal cord at a level corresponding to that of the mediastinal tumor disclosed in the roentgenograms. In view of the fact that the neurologic level of compression of the spinal cord corresponded to the situation of the shadow in the roentgenograms, a diagnosis of mediastinal and intraspinal perineurial fibroblastoma of the dumb-bell type was made. Because of the character of the tumor, the patient was seen jointly in consultation, and a one-stage operation was considered to be the operation of choice, unless contraindicated at the time of operation. As the intraspinal portion of the tumor was the most important factor in producing the symptoms and involved the most important structures, it was deemed advisable to expose this portion of the tumor first, and, as the mediastinal portion was large, we felt that it should be removed through a separate incision.

Operation was carried out, April 16, 1934. Choice of the method of administering the anesthetic was important in this case because the tumor was in the posterior mediastinum. Tumors in this region and of this size are usually very adherent to the underlying structures, and in many instances the pleura is unavoidably opened during operative removal of the growth, producing an open pneumothorax, which may result fatally from pulmonary collapse and cardiac failure. This complication can be avoided by intratracheal anesthesia administered with a positive pressure apparatus so that the intrapulmonary pressure can be controlled. As this type of anesthesia is equally satisfactory for the removal of the spinal portion of such tumors, it was utilized in this case.

In view of the fact that laminectomy is usually performed with the patient prone on the table and mediastinotomy preferably with the patient on one side or the other, the problem of posture was solved by placing the patient in an oblique position,

midway between the prone and the lateral position. The usual incision for laminectomy was made, and the spines and laminae of the fourth, fifth and sixth thoracic vertebrae were removed. This revealed a definite compression of the spinal cord by an extradural mass, which proved to be the intraspinal portion of the dumb-bell tumor. It had eroded the intervertebral foramina between the fifth and sixth vertebrae and was at least 2.5 cm. in diameter. The tumor was dissected until it was completely exposed and movable. At this stage in the procedure it was thought best to mobilize the intrathoracic portion, and for that reason the laminectomy wound was packed with warm saline gauze packs.

The thoracotomy was performed through a posterolateral incision parallel with and about 3 inches (7.5 cm.) from the spine and extending from the fourth to the seventh rib around the angle of the scapula. The posterior third of the fifth and sixth ribs were resected and the muscles in the fifth intercostal space were divided. This exposed the larger portion of the tumor, which presented in the posterior mediastinum, immediately beneath these ribs (fig. 2). The posterior portion of the tumor was separated from its fibrous attachment to the vertebrae and from the pleura and mediastinal structures posteriorly. The depth of the tumor anteriorly was such that it was impossible to separate its anterior attachments to the pleura. At this stage the packs were removed from the laminectomy wound, and the intraspinal portion of the tumor was transfixes with sutures of silk, the ends of which were

Fig. 1.—Shadow of tumor extending from the fifth to the seventh rib in the upper left part of the thorax adjacent to the spine and mediastinal structures.

passed into the mediastinal wound, allowing traction and rotation of the intraspinal portion of the tumor and its withdrawal into the mediastinal wound (fig. 3). This permitted the entire tumor to be elevated and withdrawn from the anterior mediastinum, so that the anterior attachments of the pleura could be separated from the tumor; separation was accomplished without rupturing the pleura or entering the pleural cavity. It was necessary to separate the tumor from its attachment to the aorta laterally under direct vision, this being done without any complication, and to separate the anterior attachment of the pleura without rupturing the pleura or causing undue bleeding, which could not have been accomplished had it not been possible to mobilize the tumor. A distinct advantage of this procedure was that we were able to remove the tumor extrapleurally under direct vision, avoiding injury to any of the mediastinal structures and particularly avoiding an open pneumothorax. This is a great advantage in an operation of this magnitude, as it eliminates the hazards of serious intrapleural complications. Another distinct advantage is the excellent exposure following the removal of the tumor, permitting complete control of hemorrhage simultaneously in the mediastinum and in the spinal canal. After the hemorrhage had been controlled, the laminectomy wound was again packed with saline sponges, and the mediastinal wound, which was closed in layers, was drained with two small Penrose drains to relieve any tension on the pleura that might result from exudation of serum. After the mediastinotomy wound had been closed, the laminectomy wound was closed in layers with interrupted catgut sutures, one Penrose drain being left in place for drainage, thus obviating pressure on the mediastinum and cord that might be transmitted through the intervertebral foramina.

Following operation, the patient was transferred immediately to the oxygen chamber, where she was kept for a period of ten days. The Penrose drain in the laminectomy wound was

removed after twenty-four hours; one of the drains in the mediastinotomy wound was removed after forty-eight hours and the second after seventy-two hours. The patient's convalescence was entirely uneventful. Her highest temperature,

Fig. 2.—Drawing made at operation showing relation of the tumor to its contiguous bony structures. Inset at left demonstrates relation to aorta, spinal canal, and pleura; at right, incisions for a laminectomy and mediastinotomy.

Fig. 3.—Drawing showing method of removal of tumor.

which was 100 F., was recorded on the second postoperative day; it dropped to normal on the third day and remained normal throughout the remainder of her convalescence. She had no respiratory embarrassment, nor did any pleural complications

develop. At no time during convalescence did she show any signs of compression of the cord. She was transferred to the general floor of the hospital on the eleventh day and was dismissed to her home on the twenty-fourth day after operation, at which time she was entirely free from her preoperative neurologic symptoms. A letter received four months after operation reported that her condition was excellent, that she had no subjective symptoms, and that the function of her arm was practically as good as before operation.

DIABETIC GANGRENE OF THE FACE AND EAR COMPLICATED BY FIFTH AND SEVENTH NERVE INVOLVEMENT

A. J. BRIER, M.D., TOPEKA, KAN.

This case is presented because (1) of the rarity of the occurrence of diabetic gangrene of the face and (2) because of the unique complications that occurred subsequent to the gangrenous process.

H. M., a man, aged 24, a farmer, brought to the hospital, Dec. 16, 1933, noticed a sore lump just in front of his right ear about thirty-six hours before. He was seen by his family

Fig. 1.—Gangrenous involvement after spread of process had ceased.

physician shortly after its appearance. Local application of heat was then advised. In spite of the treatment, the condition became worse. The surrounding tissue became red, hot and swollen. The pain increased. In a few hours he complained of being short of breath. Because of the rapid progress of the local symptoms and the oncoming dyspnea he was sent to the hospital. Shortly after his admission he became quite stuporous and complained of being unable to breathe on account of "gas in his stomach."

In 1927 he had influenza rather badly. From this he recovered slowly. Immediately after this illness he was told that he had sugar in the urine. On this occasion he was advised as to his diet. While his diet was watched he gained weight and strength. Although he resumed a part of his duties, he was never able to take full part of the work on the farm.

In the summer of 1932 he "began to fall off" again, when he complained of vague stomach distress, a "ravenous appetite" and an insatiable thirst. From this point on he became progressively worse. Nothing particularly was done about his condition. His diet was regulated little if at all. The family history has no bearing on his condition.

Examination at the time of admission revealed that he was poorly nourished and, though conscious, mentally sluggish. The breathing was rapid and moderately deep.

Just anterior to the right ear there was a small hardish area of a rather angry appearance. The skin surrounding this lesion was red and swollen over an irregular area extending about 1½ inches (38 mm.) in front of the ear anteriorly, above to the hair line and below to the angle of the jaw. This area was tender. No sensory or motor disturbances were present.

Fig. 2.—Anesthetic areas within line; also paralysis of face muscles.

The pupils were equal and active.

The tongue was dry and protruded in the midline. The teeth were in good condition.

No pathologic changes were noted in the neck.

Examination showed nothing unusual about the lungs and heart.

Fig. 3.—Outline of anesthetic areas, corneal changes, motor changes and ear destruction.

The abdomen was distended, particularly in the upper half, and tympanitic over its entire area. No masses or areas of tenderness were found.

On both hands were lacerations showing low grade infection. On both heels were darkish areas about 1½ inches in diameter.

Laboratory examination disclosed: hemoglobin (Salhi), 86 per cent; erythrocytes, 4,400,000; leukocytes, 8,900; polymor-

phonuclear neutrophils, 84 per cent; lymphocytes, 15 per cent; monocytes, 1 per cent.

The urine showed a two plus reaction for albumin and a strongly positive reaction for sugar, diacetic acid and acetone.

The blood sugar was 363 mg. per hundred cubic centimeters of blood. The carbon dioxide combining power by the Van Slyke method was 28.7 volumes per cent.

The blood Wassermann reaction two days later was negative, as was the Kahn reaction.

The patient was treated in a more or less recognized way, the acidosis being considered paramount. In four or five hours he was much more comfortable. On the following day he was much better and the blood sugar came down satisfactorily. This progress was not wholly constant for the next few days, but his progress was still satisfactory.

On about December 20 the involved skin in front of the ear showed definitely gangrenous changes. This was progressive. By December 26 or 27 one had the impression that the whole ear was involved and that the extension had gone deeply into the side of the face.

By about Jan. 5, 1934, seventh nerve changes were noted. Shortly after this the skin of the right side of the face became painful and swollen, and anesthesia of the skin of the face followed. Accompanying these changes, anesthesia of the right half of the tongue and the buccal mucous membrane was observed. The tongue on protrusion deviated to the right. At about the same time a burning and redness of the right eye was noted followed by total anesthesia of the conjunctiva.

The general condition of the patient improved and by January 30 the repair of the gangrene of the face and right ear had definitely become established. The heels had gone on to gangrene and were almost healed.

Throughout the course of the illness the patient had fever, which at times produced a temperature of from 103 to 104 F. This was relieved when some drainage from the face occurred. On one of these occasions of high fever a forceps was introduced deeply into the sinus that was just anterior to the ear, liberating a large amount of pus, followed by a marked reduction of the fever.

For the next three weeks the patient gradually improved, although for a great part of this time occasional elevations of temperature occurred but never reached the high marks previously noted. There was further improvement in the condition of the previously gangrenous area. The discharge from the sinus lessened but the eye changes became slowly worse and a corneal ulcer occurred.

On his seventy-fifth hospital day the patient was thought well enough to go home. He had been thoroughly instructed as to the preparation of his diet, the use of insulin and his general welfare. He was discharged to return for observation.

At home his progress was satisfactory. He gained weight and ultimately all lesions healed and he was able to do some light work.

From time to time he was seen and some improvement was noted, as manifest by the return of sensation over the proximal portion of the face. Motor function has never improved.

September 12 he returned, when the photographs were made from which the accompanying illustrations have been prepared. At this time he is doing full time work on the farm. He is strong and his nutrition is quite satisfactory.

September 21 the patient was seen, and the following notes were made: The tongue deviates slightly to the right and is asymmetrical. There is anesthesia of the right side of the tongue and mucous membrane of the cheek. The right arch of the soft palate is relaxed. The masseter muscle of the right side does not contract. The chin can be shifted to the right but not to the left. The gums of the right jaw are quite unhealthy compared to the normal side. Temperature changes cannot be told over the anesthetic area shown in the pictures.

The right eye cannot be closed or the eyebrow raised. The nasolabial fold is smooth. The angle of the mouth droops. The right half of the platysma does not contract.

The patient states that he does not sweat on the affected side, even under goggles worn to protect the right eye.

THE EVALUATION OF SERODIAGNOSTIC TESTS FOR SYPHILIS IN THE UNITED STATES

H. S. CUMMING, M.D.

Surgeon General, U. S. Public Health Service; Chairman of Committee

H. H. HAZEN, M.D.

WASHINGTON, D. C.

FRANCIS E. SENEAR, M.D.

CHICAGO

WALTER M. SIMPSON, M.D.

DAYTON, OHIO

R. A. VONDERLEHR, M.D.

Passed Assistant Surgeon, U. S. Public Health Service

WASHINGTON, D. C.

The development of a method for the evaluation of serodiagnostic tests for syphilis in the United States has recently been completed by a committee whose membership consists of two clinical pathologists appointed by the American Society of Clinical Pathologists, two syphilologists, and two officers of the United States Public Health Service. It has been the primary aim of this committee to be guided as far as possible by the most frequently employed, most practical, but also the most reliable, practices. Each step in the evaluation plan has been carefully considered with the idea of duplicating the actual procedure that occurs when the physician in private practice collects his specimens of blood and forwards them to a serologic laboratory for examination. It is believed to be the peculiar responsibility of serologists interested in the diagnosis of syphilis to develop thoroughly practical tests. They should be efficient from a diagnostic standpoint and should possess such ready adaptability that even the collection and transportation of specimens under the most unfavorable conditions that might exist in actual practice will not interfere with their efficiency. Other factors of secondary importance are the adaptability of the test to use by other technicians, rapidity of performance, and, perhaps, the cost.

The plan that has finally been decided on consists of the collection of samples of blood from donors in various categories and the distribution of these samples from central points of collection to the laboratories of participating serologists. Serologists in this country who have described an original serologic test or a modification of such a test for the diagnosis of syphilis have been invited, and with one or two exceptions all have accepted. Those who have described more than one serologic test or modification have agreed to perform only one test in their laboratory. They may, however, delegate to another laboratory in a different city the performance of the second test. It is the purpose of this study, therefore, to appraise separately the various modifications of complement fixation methods and flocculation tests. The committee feels that only in this way will it be possible to measure fairly and impartially the efficiency of independent examinations, and to determine the most valuable combination of tests.

In the collection of the specimens, sufficient blood or spinal fluid will be taken to furnish ample and comparable samples to each participating serologist. The donors for these specimens will be carefully chosen and accurate records kept of the pertinent facts in the history and physical examination of all abnormal individuals. Reasonable care will also be exerted to insure that donors will be subsequently available for clinical examination several months later in the event that disparities exist in the laboratory reports of the participants. Specimens collected under aseptic conditions in standard glass tubes will be forwarded to the participating serologists either by regular first-class mail or by special delivery air mail. The mailing of specimens will be staggered, those to serologists in cities nearest the points of collection being delayed in order that all specimens may arrive at the laboratories of all of the serologists at approximately the same time. Reports will be submitted by the serologists at regular intervals, and these reports will be immediately compared with the clinical diagnoses of the donors. The final evaluation will take place after all the serologic examinations have been completed.

The following is a detailed description of the plan that will be followed in the study to evaluate serodiagnostic tests for syphilis in the United States.

I. SELECTION OF DONORS

1. A total of approximately 1,000 donors for blood specimens and 200 donors for spinal fluid specimens will be selected. Donors for blood specimens will be chosen from the following representative groups:

- (a) Untreated early primary syphilis in the first four weeks of the disease.
- (b) Untreated secondary syphilis with cutaneous eruptions.
- (c) Late cases of syphilis with varying amounts of treatment.
- (d) Normal, presumably nonsyphilitic individuals.
- (e) Normal, presumably nonsyphilitic women, both during menstruation and in the interim between the monthly periods.
- (f) Patients with leprosy.
- (g) Patients with tuberculosis.
- (h) Patients with malignant disease.
- (i) Patients with acute febrile disease, particularly the exanthems.
- (j) Patients with malaria.
- (k) Patients with jaundice.
- (l) A group of pregnant women.

The donors for spinal fluid specimens will be drawn from two classes—nonsyphilitic patients from hospitals and clinics for nervous and mental diseases in whom nonsyphilitic disease of the central nervous system may exist, and a group of neurosyphilitic patients from similar institutions.

2. Donors of blood specimens from the early primary syphilis group shall be of the male sex and have an untreated primary syphilitic infection in the chancre stage. They must have a darkfield positive initial lesion, which has been present for a period not greater than four weeks, and the blood specimen must be taken before the appearance of any secondary manifestations of syphilis.

3. Specimens will be collected from donors with acute febrile disease only when the oral temperature is 100 F. or higher.

II. COLLECTION OF SPECIMENS

1. All blood specimens will be drawn under aseptic conditions.

2. Blood specimens will be collected in dry sterile syringes, the blood being transferred immediately to thick-walled test tubes, without lip, which will hold at least 4 cc. of whole blood. Comparable samples will be sent to each serologist in these tubes, which will be closed by a sterile cork.

3. The specimen tubes will be cleaned before sterilization as follows:

- (a) Rinsed thoroughly in cold water.
- (b) Washed thoroughly in hot soap solution.
- (c) Rinsed clear in hot water and then immersed for twenty minutes in a solution of potassium bichromate 120 Gm., concentrated sulphuric acid 600 cc., and water 800 cc.
- (d) Washed free from acid in hot water.
- (e) Ordinary wood corks will be washed well in soap and water and finally rinsed well in tap water.
- (f) Both the glass tubes and the corks will be sterilized by autoclave or by baking. The corks will then be placed in the tubes under sterile precautions and given one baking at 180 C. for one hour.
- (g) Each batch of specimen tubes prepared in the described manner will be tested for the presence of acid and to insure sterility.

4. Whole blood specimens will be sent to all participants unless several successive specimens sent to distant points are received in a hemolyzed condition.

5. All the participating serologists have agreed to perform only one test. Certain serologists who have devised two tests have designated a second laboratory in another city in which the second test will be performed.

6. Serologists performing precipitation tests will be furnished 3 cc. of whole blood; those performing complement fixation tests will be furnished 4 cc. of whole blood.

7. A maximum of 3 cc. of spinal fluid will be furnished to all participating serologists.

8. An attempt will be made to secure spinal fluid from individual patients in quantities totaling from 40 to 50 cc. This will make it possible to give every serologist a comparable sample from the same patient. In the event that it is impossible to obtain such a large quantity of spinal fluid from the entire 200 donors, specimens from several donors of known positive or negative spinal fluid will be pooled and subsequently divided into comparable samples. No dilution of spinal fluid specimens with saline solution or other foreign substances will be permitted.

III. PREPARATION OF SPECIMENS FOR SHIPMENT

1. The tubes containing specimens will be packed in double tin mailing containers, the outer to be made of tin with a screw top, lined with heavy cardboard approximately 0.25 cm. thick; the inner container to be made entirely of tin, to measure about 5 by 20 cm., and to hold twenty tubes with ample packing.

2. The name of the participating serologist will be typewritten or printed on the label, which will be pasted with ordinary commercial mucilage on the outer tin mailing container.

3. Mailing containers, holding specimens for serologists in nearby cities, the mailing of which is being purposely delayed in order to synchronize delivery time, will be kept at ordinary room temperature.

There seems to be no reason why a given bone may not present any one of a number of anatomic variations. Thus, one petrous bone may have pneumatic spaces in the antrum region only; another may have spaces about the vestibule and canals as well, and a third may, in addition, have spaces in the petrous tip. The pneumatic spaces may vary in size from those that are small to those that give the petrosa a cellular appearance. It would seem obvious that there would be no one procedure capable of handling infections of all petrous bones. In some, drainage from antral cells would be sufficient. In others, drainage would have to be maintained forward to the internal auditory meatus along the posterior border of the petrous bone. In others, with fistulous tracts already established, drainage would need to be established for the cells extending to the petrous apex above or below, or both above and below, the labyrinth.—Hagens, E. W.: *Anatomy and Pathology of the Petrous Bone*, *Arch. Otolaryng.* 19:556 (May) 1934.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary.

SCILLONIN.—A mixture of two non-water soluble glucosides, scillonin-A and scillonin-B, derived from squill, in the proportions in which they exist in the drug; namely, about equal parts. The product is standardized so that the variation in the proportion of each glucoside is not more than plus or minus 2.5 per cent (from 50 per cent), i. e., 47.5 to 52.5 per cent. Scillonin dried in a high vacuum at 50 C. for five hours loses not more than 2 per cent of its weight.

Actions and Uses.—The cardiac action of scillonin is essentially similar to that of digitalis.

Dosage.—In cardiac decompensation, where digitalis has not been administered within one week, the average adult dose is 3 mg. (six tablets, or 3 cc., of scillonin solution) daily. The average maintenance dose is 0.5 mg. per day (one tablet, or 0.5 cc., of scillonin solution). In milder cardiac disorders, from 0.5 mg. to 1 mg. of scillonin per day (one to two tablets, or 0.5 to 1 cc., of scillonin solution) may be given.

Manufactured by the Grisard Laboratories, Inc., Winchester, Tenn. U. S. patent applied for. U. S. trademark 309,472.

Tablets Scillonin, 0.5 mg.

Solution Scillonin: Each cubic centimeter represents one milligram (1/40 grain) of scillonin, in a vehicle composed of equal volumes of glycerin and alcohol.

Scillonin occurs as a pale yellow, granular powder, possessing a slight characteristic odor and an extremely bitter taste; soluble in acetone, alcohol, ethyl acetate, glacial acetic acid, dilute alkali carbonate and hydroxide solutions, sparingly soluble in chloroform, practically insoluble in water, carbon tetrachloride, ether and purified petroleum benzene. A saturated aqueous solution is neutral to litmus. An alcoholic solution is levorotatory. Dissolve about 0.001 Gm. of scillonin in 2 cc. of acetic anhydride, followed by the addition of 0.1 cc. of sulphuric acid, agitate and cool; a rose color appears changing to violet then to green (this color reaction is due to the mixture presumably of aglucones). Dissolve about 0.2 Gm. of scillonin in 25 cc. of ethyl alcohol, add 1 cc. of sulphuric acid and heat the mixture under a reflux condenser on a steam-bath for six hours. The resinification of the presumably mixed aglucones separates in the form of yellowish brown oily droplets, which on cooling solidify into a brownish waxy mass; remove the hydrolytic residue by filtration: the filtrate contains nonhydrolyzed substances and a cleaved sugar. Boil about 2 cc. of the filtrate with 5 cc. of alkaline cupric tartrate solution: a reduction of the latter results. Dissolve about 0.1 Gm. of scillonin in 5 cc. of a 10 per cent solution of sodium hydroxide and add about 0.1 cc. of a 1 per cent solution of cupric sulphate; a violet color does not appear (absence of soluble protein). Dissolve about 0.01 Gm. of scillonin in 5 cc. of ethyl alcohol and add 0.1 cc. of a 5 per cent solution of ferric chloride; a greenish yellow color results (absence of tannins). Dissolve about 0.1 Gm. of scillonin in 5 cc. of a 10 per cent solution of sodium hydroxide solution and add 10 cc. of boiling alkaline cupric tartrate solution: no reduction of latter appears immediately (absence of free reducing sugars).

Ignite about 0.1 Gm. of scillonin, accurately weighed: the residue does not exceed 0.25 per cent. Dry about 0.2 Gm. of scillonin, accurately weighed, over sulphuric acid in a partially exhausted desiccator for forty-eight hours at 20 C.; the loss in weight does not exceed 4 per cent. Dissolve about 0.5 Gm. of scillonin, accurately weighed, in 25 cc. of 95 per cent ethyl alcohol; observe the angular rotation at 20 C.: the specific rotatory power $[\alpha]_{20/D}$ falls between -18.0 and -21.5 . Transfer about 0.5 Gm. of scillonin, accurately weighed, previously dried over sulphuric acid in a partial vacuum, to a suitable Erlenmeyer flask, dissolve in 7 cc. of alcohol, followed by the addition of 7 cc. of a mixture of 1 cc. of sulphuric acid and 25 cc. of water; connect with condenser and "reflux" on a steam-bath for six hours; disconnect the condenser; neutralize the mixture with normal sodium hydroxide solution using phenolphthalein as an indicator; add 0.1 cc. of sulphuric acid; remove the alcohol by heating on the steam-bath until reduced to about a 10 cc. volume; add 10 cc. of water, mix thoroughly and evaporate to about 10 cc.; cool and collect the separated crystalline and dark waxy resinous residue on a filter paper, wash the residue with water using three portions of 10 cc. each; dissolve the residue in warm alcohol by passing it through the filter and collecting in a tared beaker; evaporate to a pilular consistency on the steam-bath and dry for three hours at 90 C.: the amount of hydrolytic residue found is not less than 70 per cent nor more than 75 per cent.

SUPPLEE B. ACIDOPHILUS MILK.—A whole milk cultured with *Bacillus acidophilus*. It contains not less than 200 million viable *B. acidophilus* organisms at the date of manufacture and not less than 100 million at the expiration date.

Actions and Uses.—See general article, Lactic Acid-Producing Organisms and Preparations, New and Nonofficial Remedies, 1934, p. 250.

Dosage.—For adults 1,000 cc. per day, increased or decreased to meet individual requirements. When employed in infant

feeding, it may be diluted with boiled water. Supplee B. acidophilus milk must be kept in a cool place and should be used prior to the expiration date stamped on the label.

Manufactured by the Cheplin Biological Laboratories, Inc., Syracuse, N. Y. (Supplee-Willis-Jones Milk Co., Philadelphia, Pa., distributor). No U. S. patent or trademark.

Fresh whole cow's milk with a butter fat content of not less than 3 per cent is sterilized at 100 C. for two hours. After cooling to 37 C. the milk is inoculated with a twenty hour seed culture of pure strains of *Bacillus acidophilus*. After inoculation the milk is kept at 37 C. for from twenty to twenty-four hours until an acidity is reached such that 10 cc. will require for neutralization 8 cc. of tenth-normal sodium hydroxide solution, phenolphthalein being used as indicator. The product is then cooled, agitated until homogeneous and transferred to one-half pint, pint and quart bottles. The strains of *Bacillus acidophilus* used are isolated by Cheplin. To insure a high degree of activity and colonization within the human alimentary tract, the organism is freshly isolated from human intestinal contents as frequently as is found necessary through actual feeding experiments.

SODIUM MORRHUATE (See New and Nonofficial Remedies, 1934, p. 417).

The following dosage forms have been accepted:

Sodium Morrhuate 5% Solution with Benzyl Alcohol (Ulmer) 5 cc. Vials: Each cubic centimeter contains sodium morrhuate-N. N. R. 0.05 Gm., benzyl alcohol 0.03 Gm., and phenol 0.005 Gm., in aqueous solution. Prepared by the Ulmer Pharmacal Co., Minneapolis. No U. S. patent or trademark.

Sodium Morrhuate 5% Solution with Benzyl Alcohol (Ulmer) 20 cc. Vials: Each cubic centimeter contains sodium morrhuate-N. N. R. 0.05 Gm., benzyl alcohol 0.03 Gm., and phenol 0.005 Gm., in aqueous solution. Prepared by the Ulmer Pharmacal Co., Minneapolis. No U. S. patent or trademark.

DILAUDID (See THE JOURNAL, June 16, 1934, p. 2024).

The following dosage form has also been accepted:

Dilaudid Rectal Suppositories 1/4 grain: Each contains dilaudid 0.0026 Gm. (1/4 grain) in a cacao butter base.

PHENOBARBITAL SODIUM (See New and Nonofficial Remedies, 1934, p. 100).

Phenobarbital Sodium-Mallinckrodt.—A brand of phenobarbital sodium-N. N. R.

Manufactured by the Mallinckrodt Chemical Works, St. Louis. No U. S. patent or trademark.

GYNERGEN (See New and Nonofficial Remedies, 1934, p. 202).

The following dosage form has been accepted:

Ampules Gynergen Solution 1:2000, 0.5 cc.: Each ampule contains 0.25 mg. of gynergen in an aqueous solution containing a small excess of tartaric acid.

PROCAINE BORATE-SEARLE (See New and Nonofficial Remedies, 1934, p. 59).

The following dosage form has been accepted:

Tablets Procaine Borate and Epinephrine: Each tablet contains procaine borate-Searle 0.05 Gm. (3/4 grain) and epinephrine 0.0001 Gm. (3/40 grain).

HOLOCAINE (See New and Nonofficial Remedies, 1934, p. 59).

The following dosage form has been accepted:

Holocaine Solution, 1 per cent: An aqueous solution containing holocaine, 1 per cent., for ocular anesthesia by instillation. The product is not to be used for injection.

RABIES VACCINE (See New and Nonofficial Remedies, 1934, p. 378).

Mulford Biological Laboratories, Sharp & Dohme, Philadelphia and Baltimore.

Rabies Vaccine (Phenol Killed)-Mulford (See New and Nonofficial Remedies, 1934, p. 380): also marketed in packages of seven vials, each vial (one dose) containing 0.5 cc. of a 25 per cent suspension of brain tissue.

PROCAINE HYDROCHLORIDE (See New and Nonofficial Remedies, 1934, p. 60).

Procaine Hydrochloride-Squibb.—A brand of procaine hydrochloride-U. S. P.

Manufactured by E. R. Squibb & Sons, New York. No U. S. patent or trademark.

Sterile Ampules Procaine Hydrochloride-Squibb (Crystals) for Spinal Anesthesia, 50 mg.

Sterile Ampules Procaine Hydrochloride-Squibb (Crystals) for Spinal Anesthesia, 100 mg.

Sterile Ampules Procaine Hydrochloride-Squibb (Crystals) for Spinal Anesthesia, 120 mg.

Sterile Ampules Procaine Hydrochloride-Squibb (Crystals) for Spinal Anesthesia, 150 mg.

Sterile Ampules Procaine Hydrochloride-Squibb (Crystals) for Spinal Anesthesia, 200 mg.

Committee on Foods

THE COMMITTEE HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT.
RAYMOND HERTWIG, Secretary.

NOT ACCEPTABLE

1. BOWEY'S DARI-RICH SYRUP
2. BOWEY'S DARI-RICH POWDER
3. BOWEY'S PASTEURIZED DARI-RICH CHOCOLATE FLAVORED SWEETENED, PARTIALLY DEFATTED MILK

Bowey's, Inc., Chicago, submitted to the Committee on Foods (1) a syrup prepared from sucrose, water, cocoa, vanilla extract and a trace of agar called Bowey's Dari-Rich Syrup; (2) a powdered mix prepared from sucrose, cocoa, water, vanilla extract and agar (U. S. P.) called Bowey's Dari-Rich Powder, and (3) a pasteurized, chocolate flavored, sweetened, partially defatted milk, called Bowey's Pasteurized Dari-Rich Chocolate Flavored Sweetened, Partially Defatted Milk, prepared by (a) mixing partially defatted pasteurized milk (2 per cent milk fat) with "Bowey's Dari-Rich Syrup" or (b) mixing partially defatted milk (2 per cent milk fat) with sugar and "Bowey's Dari-Rich Powder."

Discussion of Name.—The name "Dari-Rich" applied to the syrup and powder phonetically implies that the products are rich in milk, whereas they contain no milk; applied to the mixture of syrup or powder and skim milk, it incorrectly suggests that the liquid ingredient is whole milk. Since a food containing whole milk has broader nutritional value than one prepared from skim milk, whole milk and skim milk foods should be carefully distinguished by name and advertising in order that the purchaser may not be misinformed.

The manufacturer was informed of the judgment of the Committee but has declined to alter the name for business reasons. These products will therefore not be listed among the accepted foods of the Committee.

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION. RAYMOND HERTWIG, Secretary.

BERKSHIRE BRAND EVAPORATED MILK

Distributor.—Reading Wholesale Grocery Company, Reading, Pa.

Packer.—The Page Milk Company, Merrill, Wis.

Description.—Canned unsweetened sterilized evaporated milk, the same as Page Brand Evaporated Milk (Sterilized, Unsweetened), (THE JOURNAL, May 30, 1931, p. 1872).

GOOD MORNING PURE FLORIDA GRAPEFRUIT JUICE

GOOD MORNING PURE FLORIDA ORANGE JUICE

Distributor.—Chas. W. Bauermeister Company, Terre Haute, Ind.

Packer.—Dr. P. Phillips Company, Orlando, Fla.

Description.—Canned Florida grapefruit and orange juices sweetened with added sucrose and retaining in large measure the original natural vitamin content; the same as Dr. P. Phillips Pure Florida Grapefruit Juice (THE JOURNAL, Jan 7, 1933, p. 43) and Dr. P. Phillips Pure Florida Orange Juice (THE JOURNAL, Dec. 3, 1932, p. 1948).

MELLOW MILK—HOMOGENIZED, PASTEURIZED

Distributor.—Wayne Creamery, Detroit.

Description.—Bottled, pasteurized, homogenized milk.

Preparation.—Milk obtained from farms licensed by the Detroit Department of Health and under the supervision of the state of Michigan is delivered cold (4 C.) to the creamery, where it is pasteurized (held at 61 C. for thirty minutes), homogenized and filled in bottles by the usual procedure (THE JOURNAL, Sept. 1, 1934, p. 681).

Analysis.—Standardized to contain not less than 3.5 per cent of milk fat.

Calories.—0.7 per gram; 20 per ounce.

Claims of Distributor.—The cream does not separate. The curd formed in the stomach is softer than that from unhomogenized milk.

KENNETT MUSHROOMS BROTH—SLICED STEMS AND PIECES—FANCY BUTTONS—SLICED BUTTONS

Manufacturer.—Kennett Square Mushroom Company, Inc., Kennett Square, Pa., subsidiary of Edward H. Jacob, Inc., West Chester, Pa.

Description.—Hothouse mushrooms; respectively broth, sliced stems and pieces, buttons, and sliced buttons; the same as Jacob Mushrooms—Broth—Fancy Buttons—Sliced—Sliced Stems and Pieces (THE JOURNAL, Sept. 15, 1934, p. 838).

IRRADIATED VITAMIN D PASTEURIZED MILK

Distributors.—

Beatrice Creamery Company, Tulsa, Okla.
Biltmore Dairy Farms, Biltmore, N. C.
Carrigan's Niagara Dairy Company, Niagara Falls, N. Y.
(Golden Guernsey and Regular).
Clover Creamery Co., Inc., Roanoke, Va.
Gardner Creamery, Gardner, Mass.
Garst Bros. Dairy, Inc., Roanoke, Va.
Hunding Dairy Company, Chicago.
International Dairy Company, Chicago.
Kitsap Dairy, Bremerton, Wash.
Laurel Hill Creamery, Gardner, Mass.
Medosweet Dairies, Inc., Tacoma, Wash.
Merriman Dairy, Waterbury, Conn. (Fernwood).
Onondaga Milk Producers, Syracuse, N. Y. (Dairyalea).
Roanoke Dairy & Ice Cream Co., Inc., Roanoke, Va.
Rosedale Dairy, Norfolk, Va.
Sanitary Farm Dairies, Inc., Houston, Texas.
Sheboygan Dairy Products Co., Sheboygan, Wis.
J. H. Story & Son Dairy, New Haven, Conn.
W. Weckerle & Sons, Inc., Buffalo.
Whiting Milk Companies, Boston and Worcester, Mass.

Description.—Bottled pasteurized vitamin D milk irradiated with ultraviolet rays.

Preparation.—The milk complies with legal requirements and is pasteurized by the standard holding method. For description of irradiation see THE JOURNAL, Oct. 7, 1933, page 1155.

Vitamins.—Clinical investigation shows this milk to be a reliable antirachitic agent, if the proper amount is used. Contains 135 U. S. P. X (Revised, 1934) vitamin D units per quart.

Claims of Distributors.—Irradiated antirachitic pasteurized milk having otherwise the flavor and food values of usual pasteurized milk.

THAMES VALLEY TOMATO JUICE

Distributor.—The Yantic Grain & Products Co., Norwich, Conn.

Packer.—Vincennes Packing Corporation, Vincennes, Ind.

Description.—Pasteurized tomato juice with added salt; retains in high degree the natural vitamin content; the same as Alice of Old Vincennes Tomato Juice (THE JOURNAL, Feb. 20, 1932, p. 640).

SATURDAY, DECEMBER 1, 1934

THE ATLANTIC CITY SESSION

The Atlantic City session of the American Medical Association (June 10-14, 1935) will be notable in many ways and unique in one particular: The Canadian Medical Association has accepted an invitation to meet with the American Medical Association on this occasion. At a joint conference of Canadian officials with the Council on Scientific Assembly recently held in Chicago, preliminary plans were developed. The general council of the Canadian Medical Association is to hold its meetings simultaneously with those of the House of Delegates of the American Medical Association. The Canadian medical profession has many economic, social and political problems of interest, which parallel considerations now being given to these topics by our own legislative bodies.

Social functions will be participated in by both organizations. The Canadian medical profession will have a prominent part in the programs of all the scientific sessions, and a duplicate set of officers will alternate in presiding over these meetings. At the opening general meeting the presidents of both organizations will read their annual addresses. Thus the speakers on this occasion, besides the usual officers of state and local organizations, will be Dr. James S. McLester for the American Medical Association, and Dr. Jonathan C. Meakins for the Canadian Medical Association. Many Canadians will take part also in the Scientific Exhibit. Special sections are being arranged on military medicine and the history of medicine and anesthesia, and all the usual sections of the American Medical Association will have their regular programs.

Because of the unusual character of this meeting, it is anticipated that the number of distinguished guests from abroad will also be larger than usual. The success of the general scientific meetings, which take place on Monday and Tuesday before the opening of the section meetings, has led to the selection of many special lecturers for the Atlantic City session, who will have from forty minutes to an hour for complete presentation of knowledge regarding various medical and surgical sub-

jects. These general scientific meetings are of the same scope as the clinical conferences held in various parts of the country under local auspices. The selection of the speakers and of the topics for these meetings lies with the Council on Scientific Assembly.

The last annual session of the Association, in Cleveland, was noteworthy for an extraordinary attendance, for the completeness of its scientific exhibit, and for the manner in which the programs of the sections covered a vast range of subjects in every medical specialty. With the participation by the Canadians, it is anticipated that the meeting in Atlantic City will be similarly broad and will at the same time present a new aspect afforded by the points of view of our Canadian visitors. It is quite a few years since the Association last met in Atlantic City. The Auditorium, built as a municipal project, offers the greatest convenience for such a meeting. All the sections and the Scientific and Technical Exhibits will be accommodated under one roof. The golf courses, the bathing and other vacation features of Atlantic City provide opportunity for relaxation and recreation as well as scientific pabulum. The accessibility to most of the large cities and to various sections of our country insures an attendance rivaling that of some of the greatest meetings ever held by the Association in other parts of the country. It is time now to begin to plan for attendance at the Atlantic City session and for what is sure to be an epoch-making event in the history of American medicine.

BISMUTH SUBNITRATE IN HYPERTENSION

Therapeutic research based on clinical observation presents the same inherent difficulties as do other forms of clinical investigation—the problem of adequate control. Probably the individual physical and mental variations of patients as well as the almost unavoidable bias of the physician interfere with such control. These factors can be minimized, however, by a critical attitude on the part of the recorder and the employment of enough patients to counterbalance largely the error due to individual variation.

Arterial hypertension offers a good example of both favorable and unfavorable factors influencing this type of study. The frequency of the condition allows the ready accumulation of data. This favorable factor is more than counterbalanced by the uncertainties of etiology,¹ varying form and degree of the hypertension, and especially by the frequent natural changes in blood pressure and symptomatology occurring in one individual from time to time. Finally, hypertension must be considered as a symptom rather than a disease per se and hence the effect of treatment on this symptom cannot necessarily be assumed to constitute a favorable treatment of the patient.

The use of bismuth subnitrate in the treatment of arterial hypertension is based primarily on the studies

1. de Wesselow, O. L. V.: Arterial Hypertension, *Lancet* 2: 579 (Sept. 15), 636 (Sept. 22), 687 (Sept. 29) 1934.

of Stieglitz.² It is founded on the conception of arterial hypertension as an arteriolar irritation of different probable etiologies, which is at least partially perpetuated by long continued fatigue of the arteriolar musculature. Eradication of the initiating factors, therefore, even when possible, is not always sufficient. It becomes rational, then, to attempt the relief of fatigue of the arteriolar musculature. It is in fulfilling this purpose, Stieglitz believes, that bismuth subnitrate aids in permitting the vitally necessary and prolonged physiologic rest of the injured structures—the medial musculature of the smaller arteries and arterioles. The mode of action of bismuth subnitrate is, he believes, the slow but continuous liberation of nitrate ions in the bowel, which permits continuous absorption of minute quantities of nitrite, since the nitrate is reduced to nitrite by the action of *Bacillus coli*.

At first glance this course of reasoning appears wholly logical. Several factors difficult of complete proof are involved. The curative effect of giving the arteriolar musculature transient artificial rest is speculative. Even more doubtful is the adequacy of such rest when produced by the theoretical absorption of minute quantities of nitrites supposedly derived from the ingestion of bismuth subnitrate. In the absence of immediate prospects of solving these involved questions the general use of this method of therapeutics should depend on the actual clinical results, since it seems unwise to discard clinically advantageous procedures of treatment because the exact mode of action is not thoroughly understood.

As a result of his studies on patients with the spastic type of arteriolar hypertension, Stieglitz evidently believes that the clinical results corroborate the theoretically good therapeutic action of bismuth subnitrate. Ayman³ was unable to duplicate these effects on fifteen carefully controlled patients. Recently Bruen⁴ also has criticized the conclusions of Stieglitz on the ground of insufficient control periods. He feels that a standardized procedure for determining the blood pressure, uniform frequency of visits during control and experimental periods, and the effect of nonspecific therapy can be provided for, which leaves only two variables apart from the long term trend; viz., adventitious influences and therapeutic actions. The effects of the latter may be readily distinguished by alternating control periods under nonspecific medication not sensibly different from the experimental medication with experimental periods under experimental medication. Thus, any alteration in the blood pressure that occurs during a period of experimental medication may be referred either to adventitious factors or to the medication, depending on its continuance or cessation on the

resumption of nonspecific medication. This procedure, according to Bruen, makes possible the prosecution of rigorously controlled experimentation on the effects of therapeutic agents in arterial hypertension.

Patients newly assigned or carried under the diagnosis of hypertension, unselected except with regard to their maintenance of cardiac compensation and regular sinus rhythm, were entered into his experimental series as they became available. All who proved amenable to the experimental routine based on the control factors previously outlined were retained except those who registered diastolic pressures regularly below 90 or who were eliminated through the development of heart failure or prolonged intercurrent illness. The final series consisted of twenty persons, ranging in age from 27 to 73 with a median of 51 years. In all these, bismuth subnitrate was without demonstrable effect on the blood pressure. The symptoms of dyspnea, palpitation, cardiac pain, dizziness and headache also pursued an independent course without reference to the administration or withdrawal of bismuth subnitrate. He therefore concludes that bismuth subnitrate by mouth, even in the largest therapeutically practicable dosage, does not develop sufficient nitrite action to exert any demonstrable effect on the blood pressure or symptoms of arterial hypertension.

PALILALIA AND GERTRUDE STEIN

The current vogue of a play called "Four Saints in Three Acts" and current interest in the writings of Gertrude Stein have been an interesting phenomenon for observation by the psychiatrists. Those familiar with such symptoms as automatic writing, palilalia, perseveration and verbigeration are inclined to wonder whether or not the literary abnormalities in which she indulges represent correlated distortions of the intellect, or whether the entire performance is in the nature of a hoax, and that Miss Stein produces her literary effusions with her tongue in her cheek. Palilalia is a form of speech disorder in which the patient repeats many times a word, a phrase or a sentence which he has just spoken. In addition, the speech tends to be uttered more and more quickly and less distinctly. For example, one patient described by MacDonald Critchley¹ was with his wife at a motion picture theater when he found himself reading aloud the captions of the films over and over again. (It has been alleged that there are many people suffering with this manifestation.) His wife, becoming annoyed, jabbed him in the ribs and said "For God's sake, Bob, shut up." But all the patient could reply was "I can't shut up. I can't shut up. I can't shut up," until eventually he did shut up because his speech became inaudible. In this case the patient was suffering from the results of an attack of epidemic encephalitis in which parkinson-

3. Ayman, David: Bismuth Subnitrate in the Treatment of Arteriolar (Essential) Hypertension, *J. A. M. A.* 98: 545 (Feb. 13) 1932.

4. Bruen, C.: The Therapeutic Efficacy of Bismuth Subnitrate in Arterial Hypertension, *Am. J. M. Sc.* 188: 21 (July) 1934.

1. Critchley, MacDonald: On Palilalia, *J. Neurol. & Psychopath.* 5: 23 (July) 1927.

ism gradually supervened. Of late, palilalia has been repeatedly mentioned as a sequela of epidemic encephalitis.

An analogous condition is palilogia, a term sometimes applied to that form of rhetoric whereby the word or sentence is deliberately repeated for purposes of emphasis. Then there is also verbal perseveration, with the same word or phrase repeated as though the original idea persisted for an undue length of time in the patient's mind to the exclusion of fresh incoming ideas. Sometimes there is echolalia, in which the patient repeats the statements or questions that have been put to him. Finally there is verbigeration, a frequent symptom in dementia praecox, in which the patient repeats the same sentence over and over again.

Now it is interesting in surveying the writings of Gertrude Stein to find that Miss Stein worked at Radcliffe with Münsterberg and that she wrote a paper, later printed in the *Harvard Psychological Review* for September 1896, under the title "Normal Motor Automatism," by Leon M. Solomons and Gertrude Stein. In their experiments, Mr. Solomons and Miss Stein attempted to investigate the limits of their own normal automatism, undertaking to see how far they could split their own personalities in a deliberate and purely artificial way. They were successful, according to B. F. Skinner,² to the extent of being able to perform many acts, such as writing or reading aloud, in an automatic manner while carrying on at the same time some other activity. Miss Stein reported that spontaneous automatic writing became easy after a little practice. Thus she said:

A phrase would seem to get into the head and keep repeating itself at every opportunity, and hang over from day to day even. The stuff written was grammatical, and the words and phrases fitted together all right, but there was not much connected thought. The unconsciousness was broken into every six or seven words by flashes of consciousness, so that one cannot be sure but what the slight element of connected thought which occasionally appeared was due to these flashes of consciousness. But the ability to write stuff that sounds all right, without consciousness, was fairly well demonstrated by the experiments.

Obviously, therefore, the writing of Miss Gertrude Stein, such as appears in her plays, books and poems, is quite the same as she developed when experimenting with spontaneous automatic writing. For those who are unfamiliar with the writing of Miss Stein, we mention the following examples from the book called "Tender Buttons":

When he could not be the longest and thus to be, and thus to be, the strongest.

This long time when he did this best time, and he could thus have been bound, and in this long time, when he could be this to first use of this long time . . .

A meal in mutton mutton why is lamb cheaper, it is cheaper because so little is more.

Mr. Skinner points out that the ordinary reader cannot infer from this writing that the author possesses

any consistent point of view, because there is seldom, if any, intelligent expression of opinion. Her writing seems to be the result of a stream of consciousness of a woman without a past. The stream of consciousness is, of course, particularly well exemplified in some of the writings of James Joyce in *Ulysses*. Mr. Skinner is convinced that this spontaneous automatic writing by Miss Stein is that of a second personality successfully split off from her conscious self, and unfortunately a personality without any background, intellectual opinions or emotions. The mere fact that Miss Stein herself occasionally appears in the midst of the writings of this second personality would seem to be the proof of the opinion.

Current Comment

PERNICIOUS ANEMIA: NATURE AND THERAPY

Recently Adams has summarized¹ for the British Ministry of Health recent advances in our knowledge of pernicious anemia. In his discussion of the investigations on etiology he cites the hypothesis, partially confirmed, that the liver stores an antianemic factor (the "liver active principle"), which is produced in the stomach as a result of enzyme action between hemopoietin (the "stomach active principle") and an unknown constituent of normal diet. It appears, moreover, that the active principle of gastric tissue is more unstable than that of liver. That of gastric tissue is destroyed by temperatures greater than 45 C., by autolysis and by prolonged digestion with pepsin or trypsin. Another difference between the two principles is that, whereas the active principle of liver is always found in the filtrate after removal of the proteins, in gastric juice a protein fraction can be obtained which holds the whole of hemopoietic activity. The fact that the two principles are not identical is a point of practical importance. A considerable portion of Adams's review concerns the potency and relative cost of different preparations used in the treatment of pernicious anemia. "At present," he states, "there is only one reliable test which can be applied to ascertain the potency of a preparation intended for use in the treatment of pernicious anemia and that is the clinical one." Hence the value assigned to whole liver, liver extracts by oral and parenteral administration, gastric tissue preparations and combinations of these must be based wholly on the assessment of clinical response. There are some advantages and disadvantages of each and some indications for one or the other. He incorporates most of these facts in a table at the end of the report. The spread in cost to the patient of the different preparations is particularly striking. This spread depends primarily on the widely varying activity of the preparations. This fact probably lacks the full appreciation of most physicians but should receive considerable study, since the results of therapy as well as the cost are at stake.

Association News

MEDICAL BROADCASTS

Columbia Broadcasting System

The American Medical Association broadcasts on a western network of the Columbia Broadcasting System each Thursday afternoon on the Educational Forum from 4:30 to 4:45, central standard time. The next three broadcasts will be as follows.

- December 6 Keep Fighting Diphtheria, W. W. Bauer, M.D.
- December 13. Shopping for Health, W. W. Bauer, M.D.
- December 20. Social Security, Morris Fishbein, M.D.

National Broadcasting Company

The American Medical Association broadcasts under the title "Your Health" on a Blue network of the National Broadcasting Company each Tuesday afternoon from 4 to 4:15, central standard time. The next three broadcasts will be as follows:

- December 4. The Quick Lunch, W. W. Bauer, M.D.
- December 11. Care of the Handicapped, Morris Fishbein, M.D.
- December 18. Fight Tuberculosis With Modern Weapons, W. W. Bauer, M.D.

ANNUAL CONGRESS ON MEDICAL EDUCATION AND MEDICAL LICENSURE

Tentative Program

The Annual Congress of the Council on Medical Education and Hospitals of the American Medical Association will be held at the Palmer House, Chicago, Feb. 18 and 19, 1935. The Federation of State Medical Boards of the United States will participate in the congress. The program follows:

MONDAY, FEBRUARY 18, 10 A. M.

Report of the Council on Medical Education and Hospitals

Ray Lyman Wilbur, M.D., Chairman, Stanford University, Calif.

Should the Number of Professional Students Be Restricted?

Raymond Walters, Litt.D., President, University of Cincinnati

The History of Medical Licensure

Henry E. Sigerist, M.D., Director, Institute of the History of Medicine, Johns Hopkins University, Baltimore.

Larger Social Aspects of Medical Education

Richard E. Scammon, Ph.D., Dean of Medical Sciences, University of Minnesota Medical School, Minneapolis.

MONDAY, FEBRUARY 18, 2 P. M.

Objectives of the Campaign Against Tuberculosis

Kendall Emerson, M.D., Managing Director, National Tuberculosis Association, New York

Education of Physicians in Tuberculosis

James Alexander Miller, M.D., Professor of Clinical Medicine, Columbia University College of Physicians and Surgeons, New York.

Some Historical Aspects of Tuberculosis

Lawson Brown, M.D., Trudeau School of Tuberculosis, Saranac Lake, N. Y.

Function of the General Hospital in the Treatment of Tuberculosis

J. A. Myers, M.D., Professor of Medicine, Preventive Medicine and Public Health, University of Minnesota, Minneapolis

TUESDAY, FEBRUARY 19, 9 A. M.

JOINT SESSION OF THE COUNCIL ON MEDICAL EDUCATION AND HOSPITALS AND THE FEDERATION OF STATE MEDICAL BOARDS OF THE UNITED STATES

Symposium Should the Practice of Radiology, Pathology and the Administration of Anesthetics Be Limited to Those Who Are Licensed to Practice Medicine?

Legal Aspects

William C. Woodward, M.D., Director, Bureau of Legal Medicine and Legislation, American Medical Association, Chicago

The Point of View of the Radiologist

B. R. Kirklin, M.D., Mayo Clinic, Rochester, Minn.

The Point of View of the Pathologist

J. P. Simonds, M.D., Professor of Pathology, Northwestern University Medical School, Chicago

The Point of View of the Anesthetist

F. H. McMechan, M.D., Secretary General, International Anesthesia Research Society, Rocky River, Ohio

The Point of View of the Surgeon

Karl A. Meyer, M.D., Medical Superintendent, Cook County Hospital, Chicago

The Point of View of the Internist

James S. McLeister, M.D., President Elect, American Medical Association, Birmingham, Ala.

The Point of View of the Hospital Administrator

Arthur C. Bachmeyer, M.D., Superintendent, Cincinnati General Hospital

Administrative Aspects

A. T. McCormack, M.D., Secretary, Kentucky State Board of Health, Louisville

The Point of View of the Licensing Board

Walter L. Biering, M.D., President, American Medical Association, Des Moines, Iowa

Are Interns Practicing Medicine?

Harold Rybins, M.D., Secretary, New York Board of Medical Examiners, Albany

TUESDAY, FEBRUARY 19, 2 P. M.

Osteopathy and Licensure

Frederick Etherington, M.D., Dean, Queen's University Faculty of Medicine, Kingston, Ont.

Post-Graduate Medical Teaching

Charles Gordon Heyd, M.D., Professor of Clinical Surgery, New York Post-Graduate Medical School, New York.

Daniel J. Glomset, M.D., Des Moines, Iowa.

Uniform Standards in Licensing Examinations

Charles B. Pinkham, M.D., Secretary, California Board of Medical Examiners, Sacramento

The Annual Dinner of The Federation of State Medical Boards of the United States will be held at the Palmer House, Chicago, on Monday, February 18, at 6:30 p. m., at which an address will be delivered by Dr. Henry E. Sigerist of Baltimore.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

CALIFORNIA

Personal.—Dr. Stanley R. Parkinson, Marysville, has succeeded Dr. James H. Barr as health officer of Yuba County. —Dr. Denver D. Roos has been named health officer of Corona, following the retirement of Dr. William S. Davis.

Cult Initiatives Defeated.—Newspapers, November 8, reported that the chiropractic initiative in California was defeated almost two to one in voting returns. A signal defeat was also indicated for the naturopathic initiative. Incomplete returns appearing in these reports showed the following figures: For the chiropractic initiative, 340,921 were in favor while 589,360 were against it, and for the naturopathic initiative, 183,809 voted for it and 307,459 against it.

Society News.—Speakers before the Los Angeles Surgical Society, November 16, included Drs. Crayton C. Snyder on "Pulmonary Abscess with Pneumothorax Complicating Partial Gastric Resection for Carcinoma of the Stomach"; Harry T. Upshaw, "Ileus Following Trauma," and John H. Breyer, "Pancreatic Injuries." All are from Pasadena.—Dr. Burrell O. Raulston spoke before the Hollywood Academy of Medicine, November 15, on "Present-Day Medical Education"—Dr. Robert R. Newell, San Francisco, addressed the San Diego Academy of Medicine, November 23, on "Recent Advances in Methods of Roentgen Diagnosis."—Dr. William L. Weber, Los Angeles, addressed the San Diego County Medical Society, November 13, on medicolegal testimony.—Dr. Clarence G. Toland addressed the Los Angeles County Medical Association, November 1, on "The Status of Medicine."

COLORADO

University News.—Dr. Oscar M. Gilbert, associate professor of medicine, University of Colorado School of Medicine, was made emeritus professor of medicine, following his recent resignation as associate professor. He has been connected with the school since 1900. Dr. Thomas D. Cunningham has resigned as assistant professor of medicine.—Dr. Philip Hillkowitz, Denver, has been appointed associate professor of chemistry at the University of Denver and will have charge of a newly established course in medical technology, Science reports.

DISTRICT OF COLUMBIA

Course in Otorhinolaryngology.—Prof. Georges Portmann, professor of otorhinolaryngology, University of Bordeaux Faculty of Medicine, will conduct a course in otorhinolaryngology in Washington, January 31-February 6. Further information may be had from Dr. James A. Flynn, 1151 Rhode Island Avenue, N.W., Washington, who is in charge of arrangements.

Society News.—At a meeting of the Washington chapter of the Pan American Medical Association, October 28, the speakers were Col. Fielding H. Garrison, Baltimore, on Spanish medicine; Dr. Fred H. Albee, New York, bacteriophage in the treatment of bone and joint infections, and Dr. Robert Gutierrez, New York, horseshoe kidney. A one minute period of silence opened the meeting in commemoration of the late Dr. Santiago Ramón y Cajal of Madrid.

GEORGIA

Science Lecture Series.—The University of Georgia Science Club is sponsoring a series of lectures to demonstrate the usefulness of laboratory work in industry and the professions, including medicine and public health. Dr. Allen H. Bunce, Atlanta, secretary of the state medical association, opened the series, October 24, with a talk on Georgia health problems.

Society News.—A symposium on anemia constituted the program of the Burke, Jenkins, Sereven Counties Medical Society at Millen, October 4; the speakers were Drs. Randall G. Brown, Garfield; Quinney A. Mulkey, Millen, and Cleveland Thompson, Millen.—Dr. George W. Fuller was elected president of the Fifth District Medical Society at its recent annual meeting, succeeding Dr. Joseph Yampolsky.—In a paper before the Fulton County Medical Society, Atlanta, November 15, Dr. Benjamin H. Clifton reviewed mortality following operation on the thyroid gland in Atlanta during the past five years. Dr. John D. Martin Jr., Atlanta, discussed "Pathologic Physiology of Burns" before the society, November 1.

ILLINOIS

Society News.—Speakers before the staff of Paris Hospital, Paris, November 1, were Drs. Harry A. Oberhelman, Chicago, and Roland M. Klemme, St. Louis, on "Tumors of the Breast" and "Diagnosis and Treatment of Brain Tumors."—Dr. Richard H. Jaffe, Chicago, addressed the Peoria City Medical Society, November 20, on endocarditis; he also addressed the dinner meeting on essential hypertension.—Dr. Oliver S. Ormsby, Chicago, gave an illustrated lecture before the Sangamon County Medical Society, Springfield, October 30, on mycotic infections of the skin.—Dr. William C. Danforth, Evanston, discussed the treatment of abortion before the Bureau County Medical Society in Spring Valley, November 6.—Dr. Ralph T. Hinton, managing officer of the Manteno State Hospital, addressed a meeting in Elgin, October 24, on "Newer Treatment for Paresis."

Chicago

Society News.—Dr. Frankwood E. Williams, New York, addressed the Illinois Society for Mental Hygiene, November 23, on "Mental Hygiene and Social Forces."—Drs. Leonard E. Markin and Irving J. Shapiro addressed the Chicago Society of Allergy, November 19, on "Role of Allergy in Genito-Urinary Diseases."—The Chicago Neurological Society was addressed, November 15, by Drs. George B. Hassin and Theodore T. Stone on "Subacute Combined Degeneration of the Spinal Cord with Epidural Hemorrhage"; Stephen W. Ranson, "Some Functions of the Hypothalamus," and Howard Zeitlin, "Unusual Tumors of the Pineal Body."—At a meeting of the Chicago Ophthalmological Society, November 19, the speakers were Drs. Palmer W. Good on "An Intranasal Operation for Restoring the Normal Function of the Lacrimal Duct"; Oscar B. Nugent, "Recession Operation with Suture Control," and Elias Selinger, "A New Treatment of Trachoma."—Dr. Bernard Myers, London, England, discussed "Essential (Thrombocytopenic) Purpura Hemorrhagica" before the Chicago Pediatric Society, November 20.—At a meeting of the Institute of Traumatic Surgery, November 20, Dr. Edson B. Fowler, Evanston, Ill., talked on "A New Operation for Habitual Dislocation of the Shoulder," and Dr. Harry R. Hoffman, "The Traumatic Neuroses."—Dr. Robert H. Crawford, Indianapolis, addressed the Chicago Society of Clinical Laboratory Technicians, November 20, on "Recent Discoveries in Anemias and Blood Volume Determination."

INDIANA

District Meeting.—At the annual meeting of the Thirteenth District Medical Society, November 7, in Michigan City, the following program was presented:

Dr. Kenneth T. Knode, South Bend, Recent Advances of Pediatrics.
Dr. George S. Bond, Indianapolis, Heart Disease in Children.
Dr. Homer G. Hamer, Indianapolis, Problems of the Prostate and the Limits of Resection.

A banquet concluded the session. Addresses were given by Dr. Everett E. Padgett, Indianapolis, on "Medical Organization from an Economic Standpoint" and Dr. Roscoe L. Sensenich, South Bend, "Present Status of Health Insurance and State Medicine."

Society News.—The Indiana State Medical Association created a section on anesthesia at its recent annual meeting.—Speakers before the Northwestern Academy of Medicine at Kendallville, October 25, included Drs. John S. Coulter,

Chicago, on "Treatment of Chronic Arthritis," and Everett E. Padgett, Indianapolis, "Medical Legislation."—Dr. Karl A. Menninger, Topeka, addressed the Terre Haute Academy of Medicine, October 5, on "Limitations in the Therapeutic Application of Psychoanalysis."—A symposium on undulant fever was presented before the Indianapolis Medical Society, November 13, by Leo P. Doyle, Ph.D., associate in animal pathology, Purdue University, and Dr. John A. MacDonald. Dr. Roy W. Scott, Cleveland, discussed vascular disease at the society's meeting, October 30.—Dr. Matthew Winters, Indianapolis, discussed "Nutritional Diseases and Infant Feeding" before the Tippecanoe County Medical Society in Lafayette, November 8.

MARYLAND

Term of Health Commissioner Extended.—Under a recent amendment to the city charter, the term of the health commissioner of Baltimore is now six years instead of the previous four year appointment. It provides that Dr. Huntington Williams' term will expire Oct. 1, 1938, instead of Oct. 1, 1935. The change was a part of the charter revision program sponsored by Mayor Jackson, and will, he expects, take the position of health commissioner out of politics. The amendment also makes it mandatory for a candidate for this office to have at least five years' actual experience in public health work performed by departments of federal, state or municipal governments.

Society News.—The Medical and Chirurgial Faculty of Maryland held a joint meeting with the Medical Society of the District of Columbia, November 16, with the following speakers: Dr. Walter Freeman, "Malaria Treatment of Neurosyphilis"; Dr. Charles Armstrong, "Etiology and Distribution of Encephalitis (St. Louis Type) in the United States"; Drs. James F. Mitchell and Alexander B. Moore, "Duodenal Ulcer: Surgical and Roentgenologic Aspects," and Dr. Henry L. Darner, "The Preliminary Care of the Cervix in Supravaginal Hysterectomy."—A recent meeting of the Allegany-Garrett County Medical Society was addressed by Drs. Lawson Wilkins and George E. Bennett, Baltimore, on "Management of Measles, with Special Reference to the Use of Convalescent Serum," and "Management and After-Treatment of Poliomyelitis," respectively.

MASSACHUSETTS

Medical Pageant.—The evolution of the concept of circulation and respiration was the theme of the 1934 medical pageant presented, November 19, by students of Tufts Medical College under the auspices of the Boston Medical History Club. The history of midwifery was portrayed by women students of the school. There was an exhibition of the texts of the characters represented, selected from the material in the Boston Medical Library. The students write their own parts in these pageants, after research into the writings of the scientists whom they are to represent. The director of the library, Mr. J. F. Ballard, does the editing. The pageants have been produced annually since 1929.

MICHIGAN

Maimonides Anniversary.—The eight hundredth anniversary of Maimonides will be observed in 1935, probably in March, in a joint celebration of the silver jubilee of the Maimonides Medical Society of Detroit. Maimonides was a physician, rabbi and sage of the twelfth century.

Society News.—Speakers before the Wayne County Medical Society, November 19, were Drs. James M. Stanton on "Problems Presented by the Constitutional Psychopath"; Harry E. August, "Newer Attitudes Toward Mental Abnormalities," and Heinrich A. Reye, "Neurotic Reactions in Marriage." All are of Detroit.—Dr. William E. Keane addressed the Bay County Medical Society in Bay City, November 14, on "Transurethral Prostatectomy."—Dr. Joseph C. Bloodgood, Baltimore, addressed a public meeting in Jackson, under the auspices of the woman's auxiliary of the Jackson County Medical Society, on cancer.

University News.—The University of Michigan Pediatrics and Infectious Disease Society met in Ann Arbor, November 23-24; speakers included Dr. Louis W. Sauer, Evanston, Ill., on "Early Diagnosis of Whooping Cough and the Use of Vaccine as a Preventive Measure"; Dr. Harold B. Rothbart, Ann Arbor, "Myasthenia Gravis in Children." The evening session, Friday, was an open forum on the endocrines with the following speakers: Drs. Elwood A. Sharp, Detroit; Robert L. Schaefer, Detroit, and John L. Law, Ann Arbor. Saturday morning was devoted to a discussion of allergy by Emma L. Wardell, Drs. David M. Cowie and Meryl M. Fenton, all of Ann Arbor, and Dr. Samuel Levin, Detroit.

Annual Clinic.—The Highland Park Physicians' Club will hold its ninth annual clinic day, December 5. According to the tentative program, the following physicians will speak:

- Dr. Edward J. Stieglitz, assistant clinical professor of medicine, Rush Medical College, Chicago, Hypertension.
Dr. John W. Carmack, associate professor of rhinology, otology and laryngology, Indiana University School of Medicine, Indianapolis, Otitis Media and Its Complications.
Dr. Arthur W. Stillians, professor of dermatology, Northwestern University Medical School, Chicago, Dermatology in General Practice.
Dr. Arthur M. Mendenhall, professor of obstetrics, Indiana University School of Medicine, Newer Things in Obstetrics.
Dr. Thomas D. Allen, associate clinical professor of ophthalmology, Rush Medical College, Chicago, Eye Manifestations of Systemic Disease.
Dr. Claud R. G. Forrester, clinical professor of surgery, Loyola University School of Medicine, Chicago, Fractures.
Dr. Edward A. W. Morgan, senior demonstrator in pediatrics, University of Toronto Faculty of Medicine, Cyanosis of the New-Born.
Dr. Ellis Fischel, associate professor of surgery, St. Louis University School of Medicine, Cancer of the Breast.
Dr. Russell L. Haden, on the staff of the Cleveland Clinic, Problem of Chronic Arthritis.

MINNESOTA

Dr. Woodworth Honored.—Dr. Elizabeth A. Woodworth, bacteriologist of the Minneapolis health department since 1913, was honorably retired on her seventieth birthday, October 30. She had been connected with the department since 1901. Associates presented her with a wrist watch. The Hennepin County Medical Society also honored Dr. Woodworth with a gift of a silver bowl bearing the following inscription: "Dr. Elizabeth A. Woodworth, for Thirty-Three Years of Unusual Service to Humanity, Hennepin County Medical Society, October 29, 1934." Dr. Woodworth is a graduate of the Minneapolis College of Physicians and Surgeons.

MISSISSIPPI

Society News.—Speakers before the South Mississippi Medical Society at a recent meeting included Drs. James S. McLester, Birmingham, Ala., President-Elect, American Medical Association, on "Deficiency Diseases as a Clinical Problem"; Eugene B. Vickery, New Orleans, "Treatment of Acute Gonorrhea"; Eugene A. Bush, Laurel, "Spontaneous Rupture of an Apparently Normal Spleen"; Thomas B. Sellers, New Orleans, "Indications for Therapeutic Abortion"; William H. Anderson, Booneville, "Appendicitis"; Van C. Temple, Hattiesburg, "Otitis Media in Infancy," and Lew Wallace, president of the Mississippi Pharmaceutical Association, "The New Pharmacy Law as It Applies to the Physicians, Druggists and the Public." Dr. Hugh L. McKinnon, Hattiesburg, conducted a round table on the toxemias of pregnancy.

MISSOURI

Tuberculosis Conferences.—The third annual clinical conferences on tuberculosis held by the St. Louis Health Department opened November 5. The first conference, November 5-22, was given over to a general consideration of tuberculosis, while the second, November 8-26, and third, November 15-December 3, were symposiums on laboratory diagnosis and on diagnosis and treatment of complications of pulmonary tuberculosis, respectively. A general consideration of the disease is the subject of the last session, November 19-December 6. The conferences were held at Isolation and Koch hospitals and were presented to interest the general practitioner.

Society News.—Speakers before the Jackson County Medical Society, November 13, were Drs. John Aull on "Vitamins A and D and the Common Cold" and John McLeod, "Trichinosis."—At a meeting of the Nodaway County Medical Society, November 7, Dr. Wilson A. Myers discussed the diagnosis and treatment of diaphragmatic hernia, and Dr. Claude J. Hunt, Kansas City, surgery of the stomach.—Dr. Richard L. Sutton, Kansas City, addressed the Cole County Medical Society in Jefferson City, October 31, on diagnosis and treatment of cancer of the skin; in the evening he gave a talk on Africa, India, Indo-China and the Arctic.

MONTANA

Society News.—Dr. Ernest D. Hitchcock, Great Falls, among others, addressed the Yellowstone Valley Medical Society in Laurel, on "Gastric Analyses."—Speakers at a meeting of the Eastern Montana Medical Association and the Northeastern Montana Medical Association at Circle in October included Drs. Everett N. Jones, Wolf Point, on "Gangrene of the Omentum with Recovery," and Malcolm D. Winter, Miles City, "Tularemia Pneumonia."—The Mount Powell Tri-county Medical Society was entertained, October 9, by Drs. Eugene G. Wilcox, Drummond, and Arthur C. Knight, Philips-

burg. In addition to the hosts, speakers included Dr. James C. Shields, Butte, and Judge D. M. Duefee, Philipsburg.—The Glacier County Medical Society is being organized, according to the *Journal-Lancet*.

NEW YORK

Program for Tuberculosis Control.—The Buffalo Board of Health has recently adopted a comprehensive, coordinated program for the control of tuberculosis. A tuberculosis division will be created in the health department, with a director who will be responsible for details concerning admission to clinics and for their clinical and nursing staffs, hospital admissions, social service, financial investigations, educational and occupational programs. The proposed program also calls for construction of a preventorium for children who show malnutrition and removal of children from homes in which there are open cases. Changes in the present arrangements for admission of patients to hospitals are also contemplated.

Society News.—Dr. Timothy B. Leary, medical examiner of Suffolk County, Boston, addressed the Medical Society of the County of Albany, November 17, on "Atherosclerosis: The Most Important Form of Arteriosclerosis, A Metabolic Disease."—Drs. Walford T. Rees, Burlington, Vt., and Leo F. Schiff, Plattsburg, addressed the Franklin County Medical Society, Malone, October 24, on "Treatment of Burns" and "Practical Management of Diabetes," respectively.—Dr. William T. Getman, Buffalo, addressed the Utica Academy of Medicine, November 15, on "Bleeding During Pregnancy and Labor—Causes, Differential Diagnosis and Treatment."—Dr. Charles J. Barone, Pittsburgh, addressed the Jamestown Medical Society, October 25, on treatment of puerperal sepsis.

Dr. Parran Resigns from Radio Advisory Council.—Dr. Thomas Parran Jr., Albany, state health officer, resigned from the public health committee of the National Advisory Council on Radio in Education, November 20, after the Columbia Broadcasting System had refused to permit him to mention control of syphilis in a radio talk on "Public Health Needs." A brief nontechnical reference to life-saving possibilities through scientific control of the disease had been approved by Levering Tyson, secretary and director of the advisory council, before the last minute ban was laid down. A bulletin from the state department of health points out that as assistant surgeon general in the U. S. Public Health Service in charge of the division of venereal diseases, as health commissioner of New York and as an official of the American Social Hygiene Association, Dr. Parran has advocated a public health attack on venereal diseases. The statement also cited the fact that a large insurance company recently ran a series of advertisements throughout the country on the menace of syphilis. Summing up the needs for public health, he mentioned syphilis as one of the problems against which a frontal attack should be made. To accomplish these results he urged a full time, well trained health officer for every city and every county; a well organized health department in each state; a simplification of the present cumbersome and disjointed federal health machinery through a federal department of health.

New York City

Third Harvey Lecture.—The third lecture of the season before the Harvey Society will be given, December 20, at the New York Academy of Medicine by Dr. Wilbur A. Sawyer, associate director, International Health Division, Rockefeller Foundation. Dr. Sawyer's subject will be "The Present Geographical Distribution of Yellow Fever and Its Significance."

Sims Statue Rededicated.—A bronze statue of Dr. James Marion Sims, eminent surgeon and gynecologist and founder of the Woman's Hospital, was unveiled in Central Park, October 21. The statue, originally dedicated Oct. 20, 1894, first stood in Bryant Park but was placed in storage several years ago when the park was torn up. Now it stands on a pedestal in the park facing Fifth Avenue and One Hundred and Third Street opposite the building of the New York Academy of Medicine. Dr. Bernard Sachs, president of the academy, Dr. George Gray Ward, representing the Woman's Hospital, John H. Finley, LL.D., editor of the *New York Times*, and W. Earle Andrews, representing the park department, made addresses at the ceremonies, and Dr. Alice Gregory, a granddaughter of Dr. Sims, unveiled the statue. Dr. Sims died in 1883.

Medical and Dental Meeting.—The fourth annual combined medical-dental meeting sponsored by the joint committee of the organized medical and dental professions of Greater New York will be held at the Hotel Pennsylvania, December 3. Papers will be presented by Drs. Samuel C. Burchell and Joseph Schroff on "The Burning Tongue" and by Dr. Isadore

Rosen on "Dermatologic Manifestations of Oral Diseases and Oral Manifestations of Systemic Diseases." At an evening session Dr. Edward C. Rosenow, Rochester, Minn., will speak on "Importance of Focal Infection as Related to Health," and Frank M. Casto, D.D.S., president of the American Dental Association, on "Transition in the Art and Science of Dentistry." Dr. Maurice O. Magid will present the results of a questionnaire sent to medical and dental colleges in the United States and Canada.

Society News.—A symposium on socialized medicine was presented before the Medical Society of the County of Queens, October 30, by Drs. Thomas Parran Jr., state health commissioner; Samuel J. Kopetzky and Nathan B. Van Etten and Goodwin Watson, Ph.D., associate professor of education, Teachers College, Columbia University. Dr. Angelo L. Soresi gave an afternoon lecture before the society, November 2, on cancer of the colon and rectum. Dr. William Bierman addressed the New York Physical Therapy Society, November 7, on "Recent Advances in the Diagnosis and Treatment of Peripheral Vascular Disease." Dr. Mervin C. Myerson addressed the Medical Society of the County of Kings, November 20, on "Petrous Pyramid Suppuration (Petrositis)" and Alexander O. Gettler, Ph.D., "The Role of Toxicology in the Medical Legal Autopsy." At a meeting of the New York Surgical Society, November 14, Dr. Mont R. Reid, Cincinnati, presented a paper on "Vascular Diseases of the Extremities," which was discussed by Drs. Louis G. Herrmann, Cincinnati; Leland S. McKittrick, Boston, and William J. Merle Scott, Rochester. Dr. Marion E. Kenworthy addressed the Women's Medical Association of New York City, November 14, on "Emotional Factors in Physical Disorders." A symposium on various phases of psychiatry and psychoanalysis was presented at a meeting of the International and Spanish-Speaking Association of Physicians, Dentists and Pharmacists, November 16, by Drs. Frank Percy, George W. Henry and Alfred Adler; Victor E. Sears, D.D.S., and Lyon Jacobs, Montreal, Canada, attorney. Dr. Boris M. Fried addressed the New York Roentgen Society, November 19, on primary carcinoma of the lung. A symposium on nonmalignant tumors of bone was presented before the New York Pathological Society and the section of surgery of the New York Academy of Medicine, November 22, by Drs. Francis Carter Wood, Raymond W. Lewis and Bradley L. Coley.

NORTH CAROLINA

State Health Officer Appointed.—Dr. Carl V. Reynolds, Asheville, president of the state board of health, has been appointed acting state health officer to succeed Dr. James M. Parrott, who died November 7. Dr. Reynolds was health officer of Asheville for twenty years and has served as president of the Buncombe County Medical Society and the Medical Society of North Carolina. Dr. Sylvester D. Craig, Winston-Salem, succeeded Dr. Reynolds as president of the state board of health.

University News.—A two day course in fractures was presented at Duke University School of Medicine, Durham, October 12-13. Physicians who gave addresses and demonstrations included Drs. Philip D. Wilson, New York; William M. Roberts, Gastonia, and Oscar L. Miller, Charlotte; H. Earle Conwell, Fairfield, Ala.; Frank Adelbert Hoshall, Charleston, S. C.; Joseph Warren White, Greenville, S. C.; Hugh A. Thompson, Raleigh; Guy W. Leadbetter, Washington, D. C., and Claude C. Coleman, Richmond. A similar course was given for Negro physicians, October 16.

Society News.—Dr. Francis Bayard Carter, Durham, addressed the Guilford County Medical Society, Greensboro, November 1, on "Management of Breech Presentations." Dr. Robert A. Ross, Durham, among others, addressed the New Hanover County Medical Society, Wilmington, September 20, on "Functional Uterine Bleeding." The Wayne County Medical Society celebrated the thirtieth anniversary of its organization at a banquet, October 5, in Goldsboro. Dr. Claude C. Coleman, Richmond, Va., made an address on injuries to the brain. Drs. Paul H. Ringer, Asheville, president-elect of the state medical society; Charles S. Mangum, dean, University of North Carolina School of Medicine, Chapel Hill, and Wilburt C. Davison, dean, Duke University School of Medicine, Durham, made impromptu talks.

OHIO

Personal.—Dr. Max M. Zininger has been appointed assistant dean at the University of Cincinnati School of Medicine, and Lawrence O. Morgan, Ph.D., has been promoted to associate professor of anatomy.

Health Officers' Meeting.—The fifteenth annual conference of health commissioners with the state department of health was held in Columbus, November 14-16. Among speakers were Drs. Frank G. Boudreau, acting chief of the Health Section of the League of Nations, Geneva, Switzerland, formerly connected with the state department of health; Henry J. Gerstenberger, Cleveland, on "Tuberculosis in Children and the Mantoux Test"; Arthur G. Helmick, Columbus, "Nutritional Fads and Facts from the Viewpoint of the Clinician," and Clayton C. Perry, Cleveland, "Anebirosis." Dr. William G. Rhoten, Wooster, was elected president.

PENNSYLVANIA

Illegal Practitioners Prosecuted.—A list of illegal practitioners prosecuted by the bureau of law enforcement of the department of public instruction during the period January 1 to October 1 includes the following cases in which the defendants were convicted:

Mrs. M. W. Rhone, Mount Union, fined \$10 and costs.
V. M. Domke, Philadelphia, six months imprisonment.
John K. Rastakis, Greencastle, fined \$200 and costs.
G. A. Statti, McKees Rocks, fined \$50 and costs.
A. M. Bailey, Philadelphia, fined \$100 and costs.
J. F. English, Shamokin, fined \$100 and costs.

Philadelphia

Personal.—The Physicians' Square Club gave a testimonial dinner, October 30, in honor of Dr. Joseph B. Wolfe, who is resuming practice after several months' illness.

Gross Lecture.—Dr. Shields Warren, Boston, will deliver the annual Gross Lecture of the Pathological Society of Philadelphia, December 13, on "Recent Advances in the Pathology of the Thyroid Gland."

Society News.—Speakers before the Philadelphia Pediatric Society, November 13, were Drs. Milton Rappaport, on "The Antirachitic Value for Infants of Irradiated Evaporated Milk"; William H. Crawford, Highland Park, Ralph M. Tyson and Miss Katharine Enright, "Weight Loss in the New-Born," and Damon B. Pfeiffer and Jonathan K. Williams-Wood, Willow Grove, Pa., who reported a case of cancer of the transverse colon in a 7 year old boy. Asthma and sensitization were topics of a symposium presented before the Philadelphia County Medical Society, November 28, by Drs. Richard A. Kern, James A. Clarke Jr. and Harry B. Wilmer. Dr. Albert C. Furstenberg, Ann Arbor, Mich., addressed the section on otolaryngology of the College of Physicians of Philadelphia, November 21, on "Osteomyelitis of the Skull and Osteogenic Processes in the Repair of Cranial Defects." Drs. Bernard J. Alpers and Joseph C. Yaskin, among others, addressed the Philadelphia Neurological Society, November 23, on "Recurrent Subarachnoid Hemorrhage."

Pittsburgh

Society News.—Speakers at the meeting of the Allegheny County Medical Society, November 20, were Drs. Joseph S. Baird, on "Preventive Treatment of Measles"; Harry M. Margolis, "Conditions Masquerading as Arthritis," and Theodore O. Elterich, "Gonorrhea in the Child." Dr. C. Howard Marcy, among others, addressed the Pittsburgh Academy of Medicine, November 13, on "The Race Factor in Tuberculosis, with Special Reference to the Negro." Dr. John S. Lewis Jr., Youngstown, Ohio, presented a paper on multiple urograms before the Pittsburgh Urological Association, November 13.

TENNESSEE

Sectional Meeting.—The eightieth semiannual meeting of the Middle Tennessee Medical Association was held in Lawrenceburg, November 8-9. Speakers included Drs. William S. Rude, Ridgetop, on "Intestinal Tuberculosis"; Carl R. Crutchfield, Nashville, "Cancer of the Lip and Jaw"; Leonard W. Edwards, Nashville, "Indications for Surgical Treatment of Gastric and Duodenal Ulcer," and Leo C. Harris, Lawrenceburg, "Management of Typhoid Fever." The address of the president, Dr. Theodore Morford, Nashville, was on health insurance. Dr. James R. Connell, Adams, was elected president.

Society News.—Dr. Edwin L. Ellis, Maryville, was elected president of the East Tennessee Medical Association at the annual meeting in Maryville, October 2. Drs. Claude E. Tubbs, Sparta, and James Fred Terry, Cookeville, addressed the Five County Medical Society (Cumberland, Overton, Putnam, Jackson and White counties), September 20, on iritis and hemorrhage in obstetrics, respectively. At a meeting of the Dyer, Lake and Crockett Counties Medical Society, October 3, speakers were Drs. John O. Manier, Nashville, president of the Tennessee State Medical Association, on "The Program for Reorganization of the State Health Department"; Harrison

H. Shoulders, Nashville, secretary of the association, "State Medicine," and Lucius C. Sanders, Memphis, "Diseases of the Colon."—Drs John L. Cooley and Olango G. Hughes, Chattanooga, addressed the Hamilton County Medical Society, Chattanooga, November 15, on "Diseases of the Rectum" and "Intestinal Intoxication," respectively.—Dr. Albert Weinstein addressed the Nashville Academy of Medicine and Davidson County Medical Society, November 13, on "Diagnosis and Treatment of Addison's Disease."

TEXAS

Surgeons' Meeting.—Drs. Gordon B. New, Rochester, Minn., and Edwin P. Sloan, Bloomington, Ill., were guest speakers at a meeting of the Texas Surgical Society in Houston, October 8-9, discussing "Current Problems in Reconstructive Surgery of the Face and Neck" and "Procidencia," respectively. Dr. Ernst W. Bertner, Houston, was elected president and Dr. Richard J. White, Fort Worth, secretary.

Society News.—A symposium on treatment of syphilis was presented at a meeting of the El Paso County Medical Society, September 10, by Drs. Adolf W. Multhaupt, Leslie M. Smith and Chester D. Awe, El Paso; Dr. Robert B. Homan, El Paso, spoke on "The Value and Limitations of the X-Rays in the Diagnosis of Pulmonary Tuberculosis."—Drs. Byron Arthur Jenkins and Gustave E. Henschen, Sherman, addressed the Grayson County Medical Society, Sherman, September 12, on "External Heat as a Cause of Fever in Children" and "Backache," respectively.—Dr. Leonard A. Myers, Houston, among others, addressed the Harris County Medical Society, Houston, September 12, on "Gas Bacillus Infection."—Speakers before the Jefferson County Medical Society, Port Arthur, September 10, were Drs. Frank J. Beyt, Port Arthur, on "Recent Advances in Treatment of Pertussis" and Leslie C. Powell, Beaumont, "Carcinoma of the Cervix."—Mrs. Margaret Sanger, New York, addressed the Dallas County Medical Society, November 22, on "Operation of Birth Control Clinics."

WISCONSIN

Society News.—Speakers at a meeting of the Vernon-Monroe-Juneau Counties Medical Society, October 4, were Drs. Harold E. Marsh and Herbert W. Virgin Jr., Madison, on "Management of Heart Disease" and "Fractures of Hands and Feet," respectively.

Weyauwega Honors Dr. Jones.—The fiftieth anniversary of Dr. Edward H. Jones's entrance into medical practice was celebrated by the town of Weyauwega, November 4, with a reception arranged by the Lions Club and attended by more than 600 persons. Among the audience were the first child at whose birth Dr. Jones officiated, now a woman of 50, and the latest, a month old infant. Dr. Jones began his practice in Weyauwega Nov. 8, 1884, shortly after his graduation from Rush Medical College, Chicago. He has for many years been president of a local bank and for years was president of the town school board.

GENERAL

Personal.—Drs. Hugh S. Cumming, surgeon general of the U. S. Public Health Service, Washington, D. C.; Bolivar J. Lloyd of the Public Health Service and the Pan-American Sanitary Bureau, and Kendall Emerson, executive secretary of the National Tuberculosis Association and the American Public Health Association, attended the Pan-American Sanitary Conference, which opened in Buenos Aires, November 12.

New Forms for Hospital Records.—A committee of the American Sanatorium Association, assisted by the staff of the National Tuberculosis Association, has devised a set of twenty-three new forms for uniform and complete records of patients in sanatoriums for tuberculosis. It is stated that the new forms will simplify the collection of statistics by making all information about a given patient available for instant consultation. Dr. Everett Morris, Auberry, Calif., was chairman of the committee, which spent two years in its work. The forms are published by the Livingston Press, Livingston, N. Y.

Board of Psychiatry and Neurology.—In the announcement of the formation of the American Board of Psychiatry and Neurology in *THE JOURNAL*, November 17, page 1547, the names of Drs. Clarence O. Cheney, Louis Casamajor and Edwin C. Zabriskie, all of New York, were omitted. These physicians compose a committee to consider plans for examinations, credentials and forms for application blanks.

Clinical Meeting.—Dr. Cyrus C. Sturgis, Ann Arbor, Mich., was elected president of the Central Society for Clinical Research at the annual meeting in Chicago, November 2-3, and

Dr. Lawrence T. Thompson, St. Louis, was reelected secretary. The scientific program included the following speakers:

Dr. Edward L. Tuohy, Duluth, Minn., An Introduction to the Subject of Bone Marrow (Sternal) Biopsies

Dr. Adolph Sachs, Omaha, Iron and Copper in Human Blood

Dr. Willis M. Fowler and Adelaide P. Barer, Ph.D., Iowa City, Iron Retention Following the Oral Administration of Ferric Ammonium Citrate in Hypochromic Anemia

Drs. Charles A. Doan, George M. Curtis and Bruce K. Wiseman, Columbus, The Role of the Spleen and the Efficacy of Emergency Splenectomy in Acute Erythroclastic and Thromboclastic Crises and in Hypoplastic Anemia

Drs. Robert T. Porter and Walter L. Palmer, Chicago, Studies on the Intrinsic Factor (Castle) in Subacute Combined Cord Degeneration Without Anemia

Drs. J. Murray Kinsman and John Walker Moore, Louisville, Effect of Fever on the Circulation

Dr. Edwin G. Bannick, Rochester, Minn., Diagnostic Features of Acute Pancreatitis

Dr. Harold Feil, Cleveland, A Clinical Study of the Electrocardiograms and of the Phases of Cardiac Systole in Pellagra

Society News.—Dr. Buford G. Hamilton, Kansas City, was chosen president-elect of the Central Association of Obstetricians and Gynecologists at the annual meeting in New Orleans, November 1-3, and Dr. Willard R. Cooke, Galveston, Texas, was installed as president. Drs. Jean Paul Pratt, Detroit, and Ralph A. Reis, Chicago, were elected vice president and secretary, respectively. The next annual meeting will be held in Omaha in October 1935.—The American Therapeutic Society has set the date for its 1935 meeting for June 7-8, at the Hotel Traymore, Atlantic City.—The Federation of American Societies for Experimental Biology, comprising the American Physiological Society, the American Society of Biological Chemists, the American Society for Pharmacology and Experimental Therapeutics and the American Society for Experimental Pathology, will hold its annual meeting in Detroit, April 10-13, 1935.—The American Institute of Nutrition will hold its second annual meeting in Detroit, April 10, 1935.—The Society of American Bacteriologists will hold its annual meeting in Chicago, December 27-29, under the presidency of Dr. Milton J. Rosenau, Boston.

Twenty-Five Years of Mental Hygiene.—The National Committee for Mental Hygiene celebrated the twenty-fifth anniversary of its founding at an afternoon meeting followed by a dinner at the Waldorf-Astoria, New York, November 14. At the afternoon session the subject of discussion was "The Challenge of Childhood," with Dr. Ira S. Wile, New York, Carleton W. Washburne, Ph.D., Winnetka, Ill., and Dr. James S. Plant, Newark, N. J., as speakers. At the dinner, speakers were Dr. Adolf Meyer, Baltimore, one of the founders of the committee, who traced the development of the organization, James R. Angell, LL.D., president of Yale University, New Haven, who spoke on mental hygiene in education; Dr. Milton J. Rosenau, Boston, mental health in the public health movement; Dr. Clarence M. Hinckes, New York, director of the committee; Dr. Arthur H. Ruggles, Providence, R. I., president of the committee; Hon. Jacob Gould Schurman, former president of Cornell University, and Mr. Clifford W. Beers, New York, founder of the mental hygiene movement and secretary of the committee. The last four discussed activities and plans for the future. In recent years the committee has given attention to preventive work, notably in the establishment of child guidance clinics in which early tendencies toward mental difficulties may be corrected. Among accomplishments of the movement have been also the amending of laws to make possible more enlightened care, planning of hospital construction and the establishment of a uniform system of statistical reporting.

HAWAII

Society News.—A symposium on roentgen rays constituted the program before the Honolulu County Medical Society, November 6. Speakers at the October meeting of the society included Lieut. Comdr. Paul P. Maher, on "X-Rays in Duodenal Ulcer"; Lieut. Comdr. Harold E. Ragle, "Histamine in Gastric Analysis," and Lieut. Bartley W. Hogan, "Forced Spinal Fluid Drainage in Pneumococcal Meningitis." Comdr. Lester L. Pratt exhibited motion picture films on thoracoplasty. This program was held at the U. S. Naval Hospital at Pearl Harbor.

CORRECTION

Grade Made in Examination.—The Wisconsin State Board of Examiners requests publication of a correction in the report of its June examination, published in *THE JOURNAL*, November 17, page 1563. The applicant from the Woman's Medical College of Pennsylvania received an average grade of 83.31 per cent, instead of 77 per cent, as at first reported.

The Present Position of Radium Therapy

The fifth annual report of the National Radium Trust and Radium Commission for 1933-1934 shows the present state of radium therapy in this country. The amount of radium owned by the trust is just over 19 Gm., which is sufficient for the needs of the various centers. Owing to change in technic, containers of a type now regarded as obsolete have been broken down and new ones substituted for them. The trust is awaiting with interest the results of a scheme of research that is being carried out at the Radium Institute under the supervision of a special governing body, concerning "beam therapy," in which use is made of a highly penetrating beam of rays directed on the malignant growth from a large quantity of radium (what used to be called a "bomb") not in direct contact with the body.

A PHYSICAL RESEARCH

Cornish radium, lent by the trust to the National Physical Laboratory, has been used in an investigation made with the object of enabling gamma-ray dosage to be measured in terms of the roentgen, the ionometric unit adopted internationally for the measurement of x-ray dosage. The roentgen represents a certain degree of ionization of air, which can be determined by suitable ionization chambers. These may be (a) small closed "air-wall" chambers in which the measured volume of ionized air is prescribed by enclosing walls composed of some light element, the whole chamber being enveloped by the beam radiation, or (b) large parallel-plate "free-air" chambers in which a narrow beam of radiation is used and the measured volume of ionized air is not prescribed by boundary walls but is wholly surrounded by air. Preliminary measurements indicate that in the case of gamma rays scattered radiation plays a prominent part and that only when a narrow beam of radiation is used and the walls of the air-wall chamber are thin do the results agree with those from the free-air chamber. If the walls are thick, or if a wide beam of radiation is used, the results from the air-wall chamber are much higher than those from the free-air chamber. It appears likely that it will be possible to specify conditions under which the roentgen can be realized in the gamma ray region with sufficient accuracy for present purposes.

THE DEVELOPMENT OF CENTERS

Both efficiency and economy require that patients should be brought to the centers, which possess fully equipped clinics and specialist staffs, rather than that radium should be taken to patients. The commission also hopes that a policy will be adopted of "pooling" the radium lent by it with that which is the property of the hospitals, and the use, in a single scheme, of the total stock within the center. Economy of radium time requires an adequate number of beds for the accommodation of a large number of patients. The modern tendency to combine treatment by x-rays with that by radium is further reason for the concentration of treatment at the centers. Finally, if the hopes of those using beam therapy are realized, this will be another reason for concentration.

THE GRADUATE SCHOOL OF RADIOTHERAPY

The efficiency of the graduate school at Mount Vernon Hospital, London, has been increased by the appointment of a physicist. The school has four resident appointments—two at the hospital and two at the Radium Institute—which afford a fine opportunity for learning the technic and possibilities of

radium treatment. In conjunction with the British Institute of Radiology, a course of radiotherapy was held and was attended by twenty-two candidates. At the request of the London School of Hygiene and Tropical Medicine, a demonstration was held for a class preparing for the Diploma in Public Health.

ONE GRAM UNIT THERAPY

In August 1932, 1 Gm. units were put at the disposal of the Cancer Hospital, the Middlesex Hospital and University College Hospital, for the purpose of ascertaining the value of this unit in the treatment of malignant disease. It has been in continuous use at these hospitals for nineteen months. In the year ended April 1, 1934, 251 cases were treated. They included growths in the tongue and mouth, lip, cheek, tonsil, pharynx, larynx, antrum, breast and penis. The commission thinks that five years must elapse before the value of the treatment can be assessed but that an interim report this year would be of value, chiefly perhaps in differentiating, without attention to variations in technic, between the results of the several methods used in various sites. An investigation directed to this end is in progress.

FUTURE DEVELOPMENTS

The technic of radium treatment has developed to standard forms. One feature of this evolution is the demand for large quantities of radium for use outside the body, preferably at an appreciable distance—several inches—from the skin. The quantity usually considered necessary for effective action when used at a distance is at least 1 Gm. This unit is in use in three hospitals. The commission learns that it is likely to serve a very useful purpose. No doubt the experience gained will enable those practicing this form of treatment to use larger units with greater confidence. Since the end of 1933 the Radium Beam Therapy Research Board has had under investigation treatment with a 5 Gm. unit.

Short Wireless Waves in the Treatment of Disease

The treatment of chronic inflammation, especially of deep-seated structures, by short waves, similar to those used in broadcasting, is already popular on the continent of Europe. The first report of their use in England has been published in the *British Journal of Physical Medicine* by Dr. W. J. Turrell, medical officer to the electrotherapy department at the Radcliffe Infirmary, Oxford. These waves are usually only from 6 to 30 meters long and are generated by thermionic valves or by a spark gap machine. They can be passed into a patient without any contact between him and the source of the current. While the surface of the body remains comparatively cool, heat is generated in the tissues within. Dr. Turrell tested the effects of these short waves on white of egg and on pieces of bullock's liver. He found that they differ from those used in diathermy, in which the electrodes are in contact with the patient's body, in the more violent oscillations of an electromagnetic nature set up in the treated tissues. He obtained the best results in the treatment of parts connected with or closely underlying bony structures and in inflammatory conditions closely beneath the surface. Pain unrelieved by other methods yielded to this method. A great difficulty is the cost of the apparatus, as the power required to produce these short waves is much greater than for longer ones.

International Congress on Life Assurance Medicine

An international congress on life assurance medicine will be held in London from July 23 to July 27, 1935. This conference is the first of the kind since 1903 and the first to be held in this country. The president will be Dr. Langdon Brown, regius professor of medicine in the University of Cambridge. The principal subjects for discussion will be methods of estimating risks, the prognosis of hypertension, the acceptance of persons with glycosuria, gastroduodenal ulceration and life

assurance, and the rôle of health service in life assurance. For physicians of Great Britain and Ireland, membership is restricted to members of the Assurance Medical Society and to such other physicians as are interested in life assurance and whose application for membership is approved by the congress committee. The honorary secretary is Dr. Otto May, 142 Holborn Bars, London, E. C. 1.

Gas Warfare

Major General C. H. Foulkes, an officer of engineers who held the position of "gas adviser" for the greater part of the war and raised, trained and commanded "the special brigade," a secret unit organized for the purpose of gas attacks, has published an interesting book entitled "Gas! The Story of the Special Brigade." He shows the horrors that may have to be guarded against in any future war. Against the well disciplined troops on the western front gas caused nearly a million casualties. What will be its effect on civilian populations ill trained and inadequately supplied with protective apparatus? He enlisted the services of the best scientific brains in the country and in the later stages of the war became the president of the Chemical Warfare Committee. Throughout the war he urged the use of gas discharged in clouds on a stupendous scale before a major attack. His plans for the unfought campaign of 1919 would probably have resulted in a decisive victory. In the latter part of the war the Germans had some minor successes with Blue Cross shells containing diphenyl chlorarsine. This was a respiratory irritant and caused sneezing. It forced the troops to remove their gas masks and expose themselves to other lethal gases. Samples of this substance were extracted from a German shell and experimented with. It was found that, when a pinch was placed on the hot plate of a stove, every one was driven out of the house and that the latest pattern of German mask, even when fitted to protect against Blue Cross shells, gave no protection against a cloud so produced. A thermogenerator was soon designed to produce this cloud. In the course of investigation an even more suitable deadly compound, diphenylamine chlorarsine, was discovered. It produced an arsenic particulate cloud that could be depended on to incapacitate the enemy completely, if only temporarily. It was discovered too late to be used in France in the war but is claimed by General Foulkes to be the most effective chemical weapon ever devised. He does not believe that future use of gas can be prevented by agreement. Its infinite possibilities in a scientific age preclude any such hope.

Variations of the Syphilitic Virus

In the September issue of the *Annales de l'Institut Pasteur*, W. Nyka publishes a research on the virus of syphilis which explains some apparent discrepancies as to the etiologic rôle of *Spirochaeta pallida* in syphilis. In spite of numerous studies, since the discovery of the spirochete of syphilis by Schaudinn in 1895, many of its biologic features remain so obscure that certain authors doubt the specific rôle of the spirochete of syphilis.

Disappearance of the spirochetes is not synonymous with cure. Grave complications often present themselves, long after disappearance of the spirochetes.

Two hypotheses have been proposed to explain this discrepancy. Either these grave complications are due to a virus other than syphilis or the latter is to be found under another than the classic form. Schaudinn leaned toward the second hypothesis; that is, the existence of an invisible form. Levaditi maintains that the nonvisible form can be regarded as an ultravirus, but this view has been accepted by few. Even Levaditi

has abandoned the claim that this ultravirus, like others, possesses the property of filtrability.

Nyka studied the question on rabbits and mice inoculated with the virus of syphilis. His conclusions are that *Spirochaeta pallida* has two distinct forms, a spirochetal and a filamentous. Between the two, one finds all stages of metamorphosis.

The virus of syphilis corresponds thus to the complex "Spirochaeta-filament" with its transitional forms. Syphilis is transmitted by the spirochete, but its rôle and existence are transitional. It disappears as soon as infection of the new host is accomplished. The filamentous form is the basic or fundamental one; hence all the typical pathologic lesions of syphilis must be attributed to this filamentous form. Such a change in morphology does not necessarily carry with it a modification of the biologic properties of the parasite. In other words, the filamentous form is as capable of producing infection as the spirochetal. The latter is a cytotropic virus, that is, can penetrate into the interior of cells and multiply there, within either the nucleus or the cytoplasm. The spirochetal form loses its spiral character within the cell and becomes transformed into a filament. Such a change, however, can occur outside the cells. In its filamentous form, multiplication by transverse division takes place and the resulting filaments are able to change back again into spirochetes. The intracellular multiplication of the parasite kills the cell, but not all types of cells are equally sensitive to the syphilitic virus. Liver cells and fibroblasts are relatively more resistant than those of the nervous or lymphatic structures. Because of the difficulty of staining the filamentous form, which the author succeeded in doing, this form has thus far escaped detection.

Ingestion of Aluminum and Cancer

In view of articles in the daily press, ascribing to aluminum, lead and other substances a cancer-producing action, a recently published experimental study denying such harmful effects is of much interest.

In the July issue of the *Annales de l'Institut Pasteur*, Bertrand and Serbescu report two series of experiments on rabbits. In both series, coal tar was applied at regular intervals to the ears of rabbits in order to produce a cancer. In series A a visible cancer resulted in 78.3 per cent of rabbits living more than forty days. No aluminum was given in this series. In series B an artificial ear cancer resulted in 50 per cent of the animals living over forty days. In this series a solution of aluminum sulphate, representing 10 Gm. of aluminum metal per hundred cubic centimeters, was placed directly in the stomach with the aid of a soft rubber urethral catheter. In series B the animals received a quantity of the solution sufficient to represent 20 mg. of aluminum metal to a kilogram of the rabbits' weight.

In neither series did the necropsies reveal any visible lesion of the stomach or intestine. The authors conclude that the rôle of aluminum or its salts in the production of cancer has been greatly exaggerated. Fear of the ingestion of the minute amounts of aluminum from the use of utensils made from this metal as well as from foods or baking powders in which alum salts are used is not justified by laboratory research.

Bleeding During the Menopause

In 1933, Quénu and Claude Béchère reported forty-four cases of metrorrhagia in patients between the ages of 40 and 50. In every case a curettage (with histologic study of the scrapings) or operation was performed. The patients were reexamined at intervals of from two to eight years.

Béchère has just added fifty-six more cases, making a total of 100 observations in six Parisian hospital services. In this second series a hysterosalpingography, iodized oil being used as a routine procedure, was done. In all cases presenting lesions, following this test, either curettage or operation was done.

A study of these 100 cases reveals that objective surgical lesions existed in only one third, while in the other two thirds the changes in the uterine mucosa were not due to a local lesion but to a functional disturbance of ovarian origin. Such a cause of uterine bleeding is observed at all ages but is most likely to be found during the menopause.

The clinical picture in the majority of cases of metrorrhagia of functional (ovarian) origin presents three main symptoms: The sudden appearance of the bleeding in a woman above 40 who has previously menstruated at regular intervals is the first of the signs. The second is a period of amenorrhea lasting two or three months, which is seen only in cases of ovarian dysfunction. The third sign is metrorrhagia lasting from eight days to six weeks or longer, but there is always an interval of amenorrhea lasting from two to three months. Bèclère calls this the "triade symptomatique."

The best method of diagnosis is exploratory curettage preceded if possible by a hysterosalpingography. These will reveal the presence of lesions necessitating operative intervention in about one third of the cases. Such measures are of no avail in the other two thirds, owing to ovarian dysfunction. If medical treatment is not successful in the latter, roentgenotherapy is indicated, to induce an artificial menopause.

The New Vincent Antistreptococcus Serum

The May 22 issue of the *Bulletin de l'Académie de médecine* contains an addition to available therapeutic agents in combating streptococcal infections. Prof. H. Vincent gives the results of the use of his new serum in 136 cases of severe infection due to the more virulent forms of streptococci. All the cases were controlled by hemoculture, which method of diagnosis should be applied at as early a period as possible. The serum should be administered in large amounts subcutaneously, intramuscularly or, if possible, intravenously. The first dose should be 100 cc. given as soon as the results of the hemoculture are positive, preferably even while the report is being waited for.

In septicemia or streptococcal meningitis the daily dose of 100 cc. suffices, but in the malignant forms of diphtheria daily doses up to 250 cc. have been given. The serum should be continued as long as the symptoms of infection persist. As soon, however, as the temperature drops, one can reduce the amount of serum injected to 30 cc. and later to 20 cc. during the four or five days after cessation of the fever. Blood transfusion at intervals is the only other treatment necessary. Blood transfusion supplies the alexins that are lacking in streptococcal infections. Epinephrine, cardiac tonics, alcohol in the form of champagne and an ample diet are necessary in certain cases. In a relatively large number the serum has been given too late to be of any avail or the doses were not large enough or not given for a sufficiently long period. The drop in temperature and disappearance of symptoms usually take place between the sixth and eleventh days after the use of the serum is begun. Cases have been observed in which a moderately high temperature persisted despite recession of symptoms, and even a negative blood culture. Such a temperature may be due to the serum itself; hence it is advisable to discontinue its use for a few days while keeping close watch on the symptoms of infection, so as to be ready to resume the serum treatment.

In the report of the results, cases are included in which death occurred from delayed or inadequate administration, as well as from double pneumonia of pneumococcal origin, gangrene following injection of turpentine to produce a local reaction, and rupture of the uterus following criminal abortion.

In 136 cases of streptococcal septicemia there were 111 cures and 25 deaths, a mortality of 18.38 per cent. The list of cures includes streptococcal arthritis, meningitis complicating skull

injury throat and ear infections, sinus thrombosis following mastoiditis, septicemia due to ethmoiditis, puerperal phlebitis of severe nature, acute endocarditis (six cures in seven cases), streptococcal empyema, general peritonitis due to puerperal infection, and hemorrhagic nephritis. No other method of treatment has given such a large proportion of cures, 81.62 per cent in 136 cases, according to Professor Vincent.

Cerebral and Abdominal Syndromes in Pneumonia in Children

Professor Nobecourt, in a lecture at the Hospital for Sick Children, emphasized the necessity of being familiar with two syndromes, the meningo-encephalitic and the abdominal, which so frequently render difficult the early diagnosis of pneumonia in children. The meningo-encephalitic syndrome can occur under one of three clinical pictures. Of these, the convulsive form occurs almost always in infants aged less than 3 years. Localized or generalized convulsions may be the first evidence of an illness, accompanied by high fever and the physical evidence of a bronchopneumonia. The other two forms, delirious and somnolent, occur in older children. The delirium is more a state of confusion and lasts only a few days, being ushered in by high fever. Somnolence is a more common symptom than delirium at the onset of a pneumonia in children. These three forms, convulsive, delirious and somnolent, may or may not be accompanied by symptoms like those of an acute cerebral or cerebrospinal meningitis, which are, however, milder and of shorter duration (two or three days). One finds cutaneous hyperesthesia, rigidity of the neck and a slight Kernig sign. At times the meningitic syndrome is quite marked in the form of vomiting, hyperesthesia, and signs of Lasègue and Kernig. These more severe symptoms generally last only a few days but may persist longer.

In these cases of meningeal syndrome in pneumonia, lumbar puncture yields a clear fluid as a rule. Micro-organisms are not found. It rarely occurs that the fluid is turbid or purulent, containing polymorphonuclears and pneumococci. The meningeal or cephalomeningeal syndromes seen at the onset in pneumonias of children belong to the group of serous or attenuated meningitis. They are rarely due to a suppurative pneumococcal meningitis.

The symptoms at the onset are more cerebral than pulmonary. In some cases the physical signs of a pneumonia are well marked, in others they are widely scattered. Often, not a single physical sign is present; that is, the pneumonia is a silent factor in the clinical picture.

Food Poisoning Due to Consumption of Duck Eggs

About a year and a half ago attention was called to an outbreak of food poisoning in Westphalia after consumption of duck eggs and probably attributable to them. Among 143 persons affected, two died. In ninety-nine of these cases, bacteria capable of producing enteritis could be established in the intestinal evacuations. Breslau's bacilli were found to be the pathologic agents in many cases of enteritis, and Gärtner's bacilli in five cases. Attention was focused on salads in which duck eggs were used as well as on the preparation of mayonnaise and puddings. In two other epidemics comprising seventy cases, apparently only in the Ruhr coal mining district, similar observations were made by H. Bruns and Fromme. Meanwhile 110 more persons became sick from the end of 1932 to the beginning of 1934. Of the total number of cases known (253) there were six deaths. Many were mild cases and scarcely came to the attention of physicians, so the sum total of cases must have been higher than recorded. After an investi-

gation there was no doubt that there was a causal connection with the duck eggs, and this was strengthened by the fact that on a Dutch duck farm (many Dutch duck eggs are sent to this locality in Westphalia) an epidemic mortality of 80 per cent was reached; in several of these fowls, evidence of the Breslau enteritis bacilli were found in all the organs, in the ovary and in the yolk of the egg and in the intestine. These pathologic agents were found in fowls of the Kaki Campbell stock, which are especially good egg layers, but other stocks also were involved.

Through repeated official warnings the use of duck eggs decreased, with a corresponding decrease in the number of cases of enteritis. Abstinence from raw duck eggs did not completely set aside the danger, because baking and roasting temperatures did not suffice in every case to kill the bacilli in the interior of the egg. Nevertheless a special hygienic control of duck eggs is necessary.

Research on Twins

In a study of the influence of heredity and environment, Prof. O. von Verschuer of the Kaiser Wilhelm Institut für Anthropologie at Berlin has divided twins into three groups: (1) those with the same heredity and environment, (2) those with the same heredity but with different environment and (3) those with different heredity and the same environment. A comparison of groups 1 and 2 shows the degree of environmental influence, that of groups 1 and 3, the degree of hereditary influence.

Influence of Environment and of Heredity

	Environment	Heredity
In body weight	85 per cent	169 per cent
In chest circumference	70 per cent	165 per cent
In height	18.5 per cent	192 per cent
In cephalic index	10 per cent	72.5 per cent

The influence of environment is related to the influence of heredity:

In body weight	as 1 2
In circumference of thorax	as 1 2.4
In height	as 1 10.4
In cephalic index	as 1 5.6

According to this study the influence of heredity is greater than has been previously assumed.

Biovular twins (those with different hereditary characteristics) develop: (1) by simultaneous fertilization of two ova (by two sperms), the time of twin formation concurring with the fertilization, and (2) in the presence of a hereditary cleavage process through fertilization of the egg and by two direction bodies (by two sperms); likewise here the time of twin formation concurs with the fertilization. In both cases the chorion and amnion are doubled; the placenta is simple or double. Unioval twins (those with the same hereditary characteristics) develop from a hereditary cleavage tendency through cleavage of the embryonic anlage. The time of twin formation concurs with the cleavage. If the cleavage has occurred before the differentiation in the embryoblast and trophoblast, examination of the ovum membrane demonstrates a double chorion and amnion; the placenta is simple or double. If, on the other hand, the cleavage takes place after differentiation, that is, after formation of the embryonic nodules, a double amnion is formed with only a simple chorion. If cleavage appears even later, if therefore the embryonic area and the primary layers are already formed, a simple chorion and amnion result; in both of the latter cases the placenta is simple.

Promoting Hereditarily Healthy Families

To promote hereditarily healthy families, in line with the aim of the present administration, there has recently been established a settlement of "Germanenhof" in Altenburg, Thuringia. In this settlement, nineteen hereditarily healthy and capable families are to be given their own homes. The

applicants and their wives must assume the duty of raising their family by two within five years and of having a third and fourth child within an additional five years. Only children considered hereditarily healthy will count. Applicants who do not or cannot fulfil these requirements must leave the family homes put at their disposal within a space of three months.

The Number of War Injured in Germany

The number of war injured in Germany naturally continues to drop. In May 1934 the total number amounted to 804,505. This number is divided according to the degree of injury in the following:

Degree of War Injury	Number Injured
30 per cent	338,461
40 per cent.. . . .	121,201
50 per cent.	135,696
60 per cent.. . . .	66,406
70 per cent.. . . .	57,349
80 per cent	30,435
90 per cent.	6,291
100 per cent	45,462

Mortality in Germany During the Year 1933

The year 1933, which showed a more favorable birth rate, gave more unfavorable results with respect to mortality than 1932. Previously the numbers for all German communities with more than 15,000 inhabitants were counted; the total number of inhabitants thus came to 29,400,000, that is, 45 per cent of the total population. The number of deaths for 1933 amounted to 305,325, that is, about 15,000 more than 1932; to every thousand inhabitants, 10.4 die as against 9.9. One of the main causes of this increase is the steadily growing number of people belonging to the advanced age classes. Especially the birth years 1860-1864 show a high rate of death as do the preceding years; therefore the typical diseases of old age are prominent among the causes of death. More people died of heart disease, apoplexy and senile debility than in 1932. More than 7,500 people died of bronchitis and pulmonary inflammations; most of these belonged to the advanced age groups. In 1933, influenza played a tremendous part in the cause of death. In the course of the epidemic in January and February 1933, 8,800 persons died, while in 1932 only 2,800 died, of this disease (THE JOURNAL, May 15, 1933, p. 1948). That the influenza epidemic was essentially the cause of this rise in mortality is to be seen from a comparison of districts that were less hit by the disease: in western, northwestern and central Germany the grip raged fiercely and in these districts the mortality was 1 per thousand higher than in 1932, while the average increase for the reich amounted to only 0.5 per thousand. On the other hand, in upper Silesia and southern Germany, which remained untouched by the wave of grip, the death rate was even lower than in 1932.

Whereas these causes of death can be influenced little, it is different in the other causes. The rate of suicide, for example, has rather decreased, as has likewise the number of fatal accidents. Infant mortality showed a marked decrease.

Is There a Labyrinthine Concussion?

A complex of clinical symptoms, especially present in cranial trauma (unilateral or bilateral difficulty in hearing, deafness, ringing in the ears, vertigo and headache) is interpreted as commotio labyrinthi or labyrinthine concussion.

Professor Voss of Frankfurt-on-Main, who has been occupied with these questions, has suggested that a summary be made of all changes in the inner ear which appear as a result of trauma to the cranium or spinal column. There is the possibility of similar symptoms in injuries on a distant part of the body, as on the feet or on the buttocks, because the percussion wave is transmitted from them through the spinal column. A number of clinical observations of labyrinthine diseases in gunshot injuries of the cranium make it certain

that both types of injuries must depend on the same or similar physical phenomena. In the small "cerebral concussions," as in commotio cerebri, it is a question of a rise in pressure in the labyrinthine secretion, which, according to the laws of hydrodynamics, may be transmitted in the direction of the percussion or to all sides. Thus under certain circumstances the labyrinthine capsule may explode, as has been proved by Voss in patients having sustained war injuries. In case of weaker impacts, it is assumed that the nerve constituents enclosed within the labyrinthine capsule may be damaged or destroyed. This theory was previously not accepted by otologists, even by Voss, on the ground that the organ of Corti, because of its double embedding in fluid, is ideally protected against lesser concussions. In estimating such cases, one should treat them as traumatic neuroses. Microscopic observations, though few, which have been recently discovered, point to an organic basis for labyrinthine concussions. It is a question of degenerative processes to the nerves and to the organ of Corti. In addition, such degenerations may develop not only through impact of the fluid but also through hemorrhages, as Voss himself has observed. Labyrinthine concussions with simultaneous fracture of the labyrinthine capsule may likewise occur. Animal experimentation, undertaken by Voss, showed consistent hemorrhages, especially in the perilymphatic spaces of the cochlea and between the branches of the cochlear nerve, while the vestibular semicircular canal apparatus remained untouched.

Voss concludes that there is a concussion of the labyrinth in the sense described. Organic changes may be the basis for these labyrinthine concussions, at least of cases of more pronounced auditory disturbance or of deafness of unresponsiveness or of poor responsiveness of the vestibular apparatus.

Marriages

WILLIAM BREENE VANDEGRIFT, Baltimore, to Miss Dorothy Elizabeth Blackman of New London, Ohio, in Oakton, Va., Augusta 10.

RAYMOND CLYDE HERRIN, Madison, Ind., to Miss Mable Elizabeth Hooper of Lake Mills, Wis., in September.

PAUL H. SCHMEDICKE, Wauscon, Ohio, to Miss Irma Lois McKelvey of Attica, Ind., in Chicago, July 7.

ELLSWORTH MORTON TRACY, Providence, R. I., to Miss Ruth Memory of Maplewood, N. J., October 13.

ARCHIBALD WILLIAM FEES, Carrolltown, Pa., to Miss Juliana Connelly of Pittsburgh, September 10.

KENNETH C. PIERCE, Dowagiac, Mich., to Miss Gertrude Eckhout of Ann Arbor, October 9.

MORDECAI M. McDOWELL, Bicknell, Ind., to Miss Elizabeth Smith of Indianapolis, November 1.

JAMES LANCASTER DENAUT, KNOX, Ind., to Miss Eleanor Erickson of Chicago, September 15.

MELBOURNE JOHN COOPER to DR. JEAN MALCOLM HEAD, both of Philadelphia, September 12.

JAMES OWEN FINNEY to Miss Margaret Pride, both of Florence, Ala., November 3.

PAUL R. HOY, Detroit, to Miss Ellagene Bowen of River Rouge, Mich., August 18.

LOUIS SMITH, Lakeland, Ga., to Miss Leila Hutcheson of East Point, June 2.

FRANCIS ARND HEGARTY to Miss Louise Brieger of Taylor, Texas, August 30.

LEON S. McGOOGAN to Miss Vera M. Kelley, both of Omaha, Neb., October 20.

LESLIE J. BOONE to Miss Bronwen F. Rees, both of Kingston, Pa., October 17.

IRENE NEUHAUSER to E. L. Gustus, Ph.D., both of Kalamazoo, Mich., July 27.

HARRY E. AUGUST to Miss Helen Shetzer, both of Detroit, October 16.

Deaths

James Marion Parrott @ Raleigh, N. C.; Tulane University of Louisiana Medical Department, New Orleans, 1895; secretary of the state board of health and state health officer; past president of the Medical Society of the State of North Carolina; fellow of the American College of Surgeons; formerly member of the state board of medical examiners; at various times served as a member of the board of directors of the State Hospital, Raleigh and member of the board of trustees of the Wake Forest (N. C.) College; connected with the Parrott Memorial Hospital; aged 60; died, November 7, of heart disease.

Philipp Fischelis @ Philadelphia; Medizinische Fakultät der Friedrich-Wilhelms-Universität, Berlin, Prussia, 1885; demonstrator of histology and embryology, Medico-Chirurgical College of Philadelphia, 1903-1909, and associate professor, 1909-1917; professor of histology, embryology and general pathology and director of laboratories in the dental school, Temple University; member of the American Association of Anatomists; for many years on the staff of the Mount Sinai Hospital; co-author of "Anatomy and Histology of the Mouth and Teeth"; aged 76; died, October 30, of angina pectoris.

William Hewson Mook @ St. Louis; Beaumont Hospital Medical College, St. Louis, 1900; assistant professor of clinical dermatology, Washington University School of Medicine; member and past president of the American Dermatological Association; served during the World War; aged 55; on the staffs of the Barnard Skin and Cancer Hospital, Barnes Hospital, De Paul Hospital, Missouri Pacific Hospital, Missouri Baptist Hospital and St. Anthony's Hospital, where he died, November 3, of heart disease, following pneumonia.

Henry Clinton Burgess @ Canandaigua, N. Y.; Syracuse University College of Medicine, 1907; member of the American Psychiatric Association and the Association for Research in Nervous and Mental Diseases; served during the World War; aged 51; medical superintendent of the Brigham Hall Hospital; on the staff of the Memorial Hospital, where he died, October 24, of an overdose of a narcotic.

David Walter McFarland @ Greens Farms, Conn.; University of the City of New York Medical Department, 1885; member of the American Psychiatric Association; in 1913 founded the Spring Hill Hospital, Hastings-on-the-Hudson, N. Y.; aged 76; in 1898 established the Hall-Brooke Sanitarium, where he died, October 26, of uremia, myocarditis and arteriosclerosis.

Charles Simonton Jordan, Asheville, N. C.; University of the City of New York Medical Department, 1890; member of the Medical Society of the State of North Carolina; veteran of the Spanish-American and World wars; aged 66; died, October 28, in the Veterans' Administration Facility, Oteen, of myocarditis, arteriosclerosis and nephritis.

John Duncan McMillan, Paris, Texas; Hospital College of Medicine, Louisville, Ky., 1885; member of the State Medical Association of Texas; past president of the Lamar County Medical Society; on the staffs of St. Joseph's Infirmary and the Lamar County Hospital; aged 75; died, August 10, of cerebral hemorrhage.

Sterling Buchanan Hinton, Franklin, Ky.; Vanderbilt University School of Medicine, Nashville, Tenn., 1916; member of the Kentucky State Medical Association; served during the World War; formerly member of the school board; aged 42; died, October 28, in the Southern Kentucky Sanatorium, of chronic nephritis.

Walter Horatio Sturgis, Hull, Mass.; Baltimore Medical College, 1895; member of the Massachusetts Medical Society; served during the World War; member of the board of health; for many years owner of a hospital bearing his name; aged 61; died, October 29, of heart disease.

Frank Wieland @ Chicago; Hering Medical College, Chicago, 1896; formerly professor of genito-urinary diseases, Hahnemann Medical College and Hospital; on the staff of the Henrotin Hospital; aged 65; died suddenly, November 18, of myocarditis and cerebral embolism.

Philip F. Gillette, Kankakee, Ill.; Northwestern University Medical School, Chicago, 1896; aged 64; formerly on the staff of the Elgin (Ill.) State Hospital; on the staff of the Kankakee State Hospital, where he died, October 27, of cerebral hemorrhage.

Manuel Fernandez y Nater, San Juan, P. R.; Bellevue Hospital Medical College, New York, 1896; member of the

Medical Association of Puerto Rico; aged 61; died, June 30, of aortic insufficiency, cardiac decompensation and pulmonary edema.

Jared Waldo Daniels @ St. Peter, Minn.; Rush Medical College, Chicago, 1889; College of Physicians and Surgeons, Medical Department of Columbia College, 1890; served during the World War; aged 67; died, October 9, of coronary occlusion.

David M. Criswell, Coshocton, Ohio; Baltimore Medical College, 1892; member of the Ohio State Medical Association; formerly member of the state legislature; city and county health officer; aged 69; died, October 21, of heart disease.

Thomas H. Baird, Otto, Texas; Tulane University of Louisiana Medical Department, New Orleans, 1888; member of the State Medical Association of Texas; aged 75; died, September 24, in a hospital at Waco, of acute nephritis.

Alexander Charles Calisch @ Oswego, N. Y.; New York Homeopathic Medical College and Hospital, 1891; served during the World War; on the staff of the Oswego Hospital; aged 63; died, September 14, of coronary thrombosis.

Arthur Frazier Shepherd, Dayton, Ohio; Medical College of Ohio, Cincinnati, 1893; member of the Ohio State Medical Association; formerly superintendent of the State Hospital; aged 69; died, October 29, of coronary thrombosis.

Robert Burns McKeage, Scranton, Pa.; Medico-Chirurgical College of Philadelphia, 1893; member of the Medical Society of the State of Pennsylvania; aged 64; died, October 2, of epithelioma of the lower lip.

Nathan Hammond @ Plainfield, Ohio; Ohio Medical University, Columbus, 1905; chairman of the county board of health; aged 61; died, October 29, in West Lafayette, of heart disease and pneumonia.

H. Francis Hunt, Jamestown, N. Y.; University of Buffalo School of Medicine, 1898; formerly on the staff of the Jamestown General Hospital; aged 66; died, October 13, of carcinoma of the liver.

Edwin A. Means, Dallas, Texas; Denver College of Medicine, 1893; member of the State Medical Association of Texas; aged 58; died, October 11, of chronic myocarditis and lobar pneumonia.

William H. Tomlinson, Swarthmore, Pa.; Hahnemann Medical College of Philadelphia, 1875; aged 89; died, October 10, of malignant papilloma of the neck and hypostatic pneumonia.

Sylvan David Kahn, Hallettsville, Texas; Tulane University of Louisiana School of Medicine, New Orleans, 1913; aged 44; died, October 13, of carbuncle of the neck and diabetes mellitus.

Winfield Scott Rowley, Indianapolis; Eclectic Medical Institute, Cincinnati, 1890; Rush Medical College, Chicago, 1891; aged 82; died, October 21, of cardiovascular renal disease.

Gifford Osborne @ Brownsville, Texas; Rush Medical College, Chicago, 1895; member of the Illinois State Medical Society; aged 61; died, September 24, of coronary sclerosis.

Charles H. Carter, Seaford, Del.; Baltimore University School of Medicine, 1895; aged 65; died, October 5, in the Delaware State Hospital Farnhurst, of ulcerative colitis.

David Orson Miner, San Diego, Calif.; University of the City of New York Medical Department, 1884; aged 74; died, October 11, in Los Angeles, of hypertrophic cirrhosis.

John W. Youngman, Paxton, Neb.; American Medical College, St. Louis, 1883; aged 79; died, July 1, in the Nebraska Masonic Home, Plattsmouth, of cardiovascular disease.

William W. Case, Nebraska, Ind.; College of Physicians and Surgeons, Keokuk, Iowa, 1886; aged 74; died, October 2, of carcinoma of the pylorus and arteriosclerosis.

Henry Frederick Gau, Cincinnati; Medical College of Ohio, Cincinnati, 1894; aged 62; died, October 21, of lymphosarcoma with metastases to the liver and lungs.

Marshall H. Galloway, Rich Pond, Ky.; Vanderbilt University School of Medicine, Nashville, Tenn., 1883; aged 82; died, October 26, of carcinoma of the spleen.

William Christopher Langhorst, Los Angeles; Northwestern University Medical School, Chicago, 1897; aged 65; died, September 26, of cerebral hemorrhage.

John Adam Quell, Brooklyn; Columbia University College of Physicians and Surgeons, New York, 1902; aged 52; died suddenly, recently, of coronary thrombosis.

Albert Joseph Croft, Chicago; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1906; aged 56; died, October 31.

Philip Gouvneur Young @ Sacramento, Calif.; Drake University College of Medicine, Des Moines, Iowa, 1908; aged 56; died, September 18, of heart disease.

David P. Hueston, Jacksonville, Ill.; College of Physicians and Surgeons of Chicago, 1888; aged 84; died, October 31, as the result of injuries received in a fall.

Arthur Joseph Burgess, Deland, Fla.; Harvard University Medical School, Boston, 1882; aged 76; died, October 18, of carcinoma of the prostate and liver.

Elmer E. Polk, Muncie, Ind.; Physio-Medical College of Indianapolis, 1886; aged 70; died, October 12, of chronic myocarditis, nephritis and arteriosclerosis.

Charles Carroll Hyde, Addison, Mich.; University of Michigan Medical School, Ann Arbor, 1876; aged 81; died, October 28, of cerebral hemorrhage.

Edward W. McEssy, Fargo, N. D. (licensed in North Dakota in 1905); aged 57; died, October 15, in a hospital at Moorhead, Minn., of heart disease.

Walter Emmett Jackson, Kansas City, Mo.; Rush Medical College, Chicago, 1895; aged 64; died, October 24, of bronchopneumonia and empyema.

Thomas J. Bond, Tahlequah, Okla.; Arkansas Industrial University Medical Department, Little Rock, 1895; aged 82; died, August 23, of carcinoma.

Robert C. Liddon, Corinth, Miss.; Maryland Medical College, Baltimore, 1900; formerly bank president; aged 55; died, October 13, of heart disease.

Howard W. Quirk, Ashtabula, Ohio; Western Reserve University Medical Department, Cleveland, 1882; aged 75; died, recently, of arteriosclerosis.

William Archibald Bolling, Lexington, Ky.; University of Louisville School of Medicine, 1891; aged 67; died, October 23, of angina pectoris.

Clive Charles McCullough, New York; Albany (N. Y.) Medical College, 1889; aged 69; died suddenly, November 11, of coronary thrombosis.

Gerhard Olaus Fortney @ Zumbrota, Minn.; Rush Medical College, Chicago, 1906; aged 51; died, October 26, of carcinoma of the stomach.

Reinard Smith Keeler, Sanford, Fla.; Jefferson Medical College of Philadelphia, 1875; aged 79; died, October 29, of pneumonia and uremia.

Merwyn R. Bibb, Chicago; Harvey Medical College, Chicago, 1902; aged 58; died, October 24, of chronic nephritis and secondary anemia.

Almon Danforth Hodges @ Boston; Harvard University Medical School, Boston, 1893; aged 69; died, October 17, of lobar pneumonia.

Alfred Richard Seebass @ Denver; Denver College of Medicine, 1893; aged 66; died, November 8, of a self inflicted bullet wound.

Richard Garrison, Toms River, N. J.; Baltimore University School of Medicine, 1901; aged 75; died, October 14, of heart disease.

T. B. Gassaway, Bartlett, Tenn.; Memphis (Tenn.) Hospital Medical College, 1902; aged 54; died, October 25, of heart disease.

William Perry Clay @ Convoy, Ohio; Starling Medical College, Columbus, 1896; aged 70; died, November 4, of carcinoma.

Hiram S. Smith @ Black Diamond, Wash.; Detroit College of Medicine, 1898; aged 65; died, October 10, of heart disease.

Wilson G. Stephens, Catawba, Ohio; Eclectic Medical Institute, Cincinnati, 1889; aged 71; died, October 21, of heart disease.

Charles Arnold Wyndham, Lisbon, Maine; Medical School of Maine, Portland, 1907; aged 52; hanged himself, September 23.

Robert Garrett Lee Lumpkin, Baltimore; Baltimore Medical College, 1892; aged 63; hanged himself, October 8.

J. E. Hawkins, Lexington, Ky.; Louisville Medical College, 1872; aged 81; died, October 2, of coronary occlusion.

Simoes Blakeney, Waldron, Ark. (licensed in Arkansas in 1905); aged 81; died, October 26, of chronic myocarditis.

James S. Hibbard @ Wichita, Kan.; Kansas City Medical College, 1900; aged 61; died, October 17, of heart disease.

Harry G. Gould, McKinney, Texas; Fort Wayne (Ind.) College of Medicine, 1884; aged 71; died, recently.

Bureau of Investigation

AARON W. RAFFELSON—IMPOSTOR

A Shrewd Swindler Who Poses as a Physician

A man who calls himself, variously, Aaron W. Raffelson, Donald Clinton Raphael, Aaron Raphael, Aaron Wolf, C. S. Julian and others, is now going about the country posing as a physician, particularly as a psychiatrist, and swindling medical men and others. According to information received from state officials in New York and police officials in Santa Fe, N. M., Raffelson is about 5 feet 5½ inches tall, aged about 23 but looks older, weighs 130 pounds, is slim and wiry in build, sometimes wears his hair bright red and other times black, has dark brown eyes, a swarthy complexion, at times wears a small mustache, and invariably goes bare-headed. He has a marked acne of the face. He speaks English fluently, also German and Yiddish.

Accompanying this article is a photograph of this impostor taken Dec. 11, 1930, by the Police Department of the City of New York at the time that he was arrested for forgery. His number in the New York City police records is B-87593. His fingerprint class is $\frac{9}{21} \frac{U}{Ra} 14$

After his arrest for forgery in 1930, Raffelson was discharged and placed on probation in the custody of the complainant. At the time Raffelson was employed by the University Settlement Society. He reported to the Society for a while and made part restitution. The Society has not seen or heard from him in the past two years.

Raffelson misuses medical certificate No. 16534 issued by the State of New York. According to the New York officials, this certificate was stolen from a woman physician of New York City. Raffelson replaced the physician's name with one of the names that he uses, Aaron Warren Raphael. According to the same source of information, Raffelson has a forged diploma from New York University dated 1933, from the Department of Psychology, School of Education. (See illustration.) He is also said to wear a Phi Beta Kappa key—stolen.

While Raffelson was in New York City, he claimed to be an M. D., gave medical treatments and wrote prescriptions for a number of people in New York State. Raffelson is evidently a shrewd and plausible scamp, and was able to take in a number of people of above average intelligence. While he was in New

Photograph of Aaron W. Raffelson, alias Aaron Raphael, alias Donald Raphael, etc., etc. It was taken by the Police Department of the City of New York, Dec. 11, 1930.

York he is said to have claimed to be a teacher at New York University, University and Bellevue Hospital Medical College, and claimed, also, to be an assistant state medical examiner. Both statements, of course, were utterly false. He has also claimed to be a graduate of the University of Oregon Medical School and the State University of Iowa College of Medicine and to have served as intern in Bellevue Hospital and to have been a research worker at the Rockefeller Foundation. All of these claims are false.

Getting wind of the fact that the New York officials were about to close in on him, Raffelson left that city and went to Santa Fe, N. M., in April, 1934. By a shrewd move on the part of Raffelson, he was able to get a letter of introduction from a gentleman of high standing in New York. As soon as he reached Santa Fe a credit organization of that city began checking up with their correspondent in New York, who reported that Raffelson's credit accounts there had been paid satisfactorily (with money, it appears, that he had obtained by swindling other New Yorkers). Santa Fe is not a large city, and it was not long before Raffelson's tendency to be obtrusive

THE TRUSTEES OF NEW YORK UNIVERSITY IN THE CITY OF NEW YORK

TO ALL PERSONS TO WHOM THESE PRESENTS MAY COME GREETING
BE IT KNOWN THAT

Aaron Warren Raphael

HAVING COMPLETED THE STUDIES AND SATISFIED THE REQUIREMENTS
FOR THE DEGREE OF

DOCTOR OF PHILOSOPHY

HAS ACCORDINGLY BEEN ADMITTED TO THAT DEGREE WITH ALL THE
RIGHTS PRIVILEGES AND IMMUNITIES THEREUNTO APPERTAINING

IN WITNESS WHEREOF WE HAVE CAUSED THIS DIPLOMA TO BE
SIGNED BY THE CHANCELLOR OF THE UNIVERSITY AND BY THE DEAN OF THE
SCHOOL OF EDUCATION PHILOSOPHY PSYCHOLOGY AND PEDAGOGY
AND OUR CORPORATE SEAL TO BE HERETO AFFIXED IN THE CITY OF
NEW YORK ON THE TWENTY SECOND DAY OF MARCH IN THE YEAR
OF OUR LORD ONE THOUSAND NINE HUNDRED AND THIRTY THREE

John I. Water
DEAN
Nancy W. Chase
CHANCELLOR

Greatly reduced photographic facsimile of a "diploma" said to have been forged by Raffelson and purporting to have been issued by New York University. Its crudity and falsity is apparent.

made him rather well known. He spoke on psychiatry before local civic clubs, and he was also said to have paid marked attention to a young woman of that city and, indeed, was "cutting quite a large swath socially." When suitable occasions presented themselves, he would flash a badge which he claimed was a police badge from the City of New York. It was, however, merely an ambulance driver's badge.

On September 4 a murder was committed in Santa Fe. Raffelson immediately jumped into the investigation of the crime with a local detective. At the postmortem he was said to have testified under oath that he was a practicing physician and that he had assisted in conducting an autopsy on the deceased.

Detective H. C. Martin of the District Attorney's Office at Santa Fe, N. M., reports that the impostor is a fast talker, intelligent, and is likely to frequent the best hotels. Raffelson is said to claim that his father's estate in Oregon is being probated and that he (Raffelson) has substantial prospects therefrom. When last seen Raffelson wore a dark blue suit, white shirt with collar attached. He is also said to carry a 32-25 automatic in holster, both pistol and holster stolen while in Santa Fe.

On the morning of September 16 Raffelson is reported to have gone to a Santa Fe garage, where he deposited a worthless check and hired an automobile for the claimed purpose of driving to Portland, Ore. Instead of heading northwest, however, he went south to the Mexican border and five days later the car was recovered in a garage at El Paso, Texas, where Raffelson had left it. When he left Santa Fe, he had cashed checks aggregating almost a thousand dollars, one drawn on a bank that doesn't exist and all made out to Aaron W. Raphael by some non-existent individual. It appears that seven warrants have been sworn out against him in Santa Fe, charging him with swindling, forgery, illegal practice of medicine, obtaining money under false pretenses, larceny by bailee, and other charges.

Correspondence

EARLY REFERENCES TO PHYSICAL ALLERGY

To the Editor:—Under current comment, September 29, you discussed the importance of physical allergy and mentioned a few old references. Although you make no claim that these are the oldest references on the subject, Dr. Richard L. Sutton Jr. in a communication, October 27, corrects you with the statement that earlier reports of physical allergy are available and he cites articles published in 1883, 1881 and 1875.

The references which Dr. Sutton cites are still not the oldest. For example, Blachez (*Bull. Soc. méd. d. hôp. de Paris* 3:262, 1872) recounts an instance of angioneurotic swellings due to exposure to cold water and to cold air or to the eating of ice. Behier (*ibid.* 3:262, 1866) describes his own case of urticaria brought on by cold water. Bourdon (*ibid.* 3:259, 1866) tells of asthma due to cold.

SAMUEL M. FEINBERG, M.D., Chicago.

MORTALITY AND MORBIDITY STATISTICS

To the Editor:—I should like to call attention to a common fallacy in the presentation of mortality and morbidity statistics, which is illustrated again by an article by Grulee, Sanford and Herron on breast and artificial feeding in *THE JOURNAL*, September 8. The fallacy consists in reporting the mortality for a group under the supervision of an organization and then comparing it with the mortality of the city or state or nation as a whole.

In this article, for instance, it is stated that the mortality for the group under the care of the Infant Welfare Society of Chicago was 11.1, which was less than one fourth of the infant mortality of the same region. Now the infant mortality of the same region is made up of all the deaths of infants from the very moment of birth. The mortality of the group under the supervision of the Infant Welfare Society is made up obviously of only those infants who came under its supervision. In a communication from Dr. Grulee I learned that none of these children came under the care of the society earlier than the third week and all of them were not under its care until the second month. It is perfectly obvious therefore that, since from one half to two thirds of all the deaths among infants occurs in the first month of life, it is entirely incorrect to compare one group, in which not one of the infants was under 3 weeks of age, with another group that has to assume the responsibility for all deaths occurring in the first three weeks.

A second fallacy is found in comparing groups with different racial distribution. In chart 1 the authors indicate the racial distribution of the people in the neighborhoods. From experience with infant welfare work it is reasonable to believe that the attendance at the baby stations was not exactly in a similar proportion as the racial groups which existed in the neighborhoods. It is well known that Italian and Russian mothers are quicker to take advantage of all sorts of medical and nursing service, guidance and advice. So one would be inclined to believe that a higher percentage of babies of Russian and Italian mothers attends the baby stations than was found in the neighborhoods. Furthermore, the neonatal rate and the infant mortality rate are much lower among infants of Italian and Russian mothers. One finds, then, in this fact of different distribution of racial groups a constant error in the comparison made by organizations with the community at large.

At the Montreal session of the American Public Health Association in September 1931, I had occasion to bring to light

similar fallacies in the reports of organizations carrying on prenatal work. It is unfortunate that more attention is not paid to some of these well known factors in statistical reports. It may be that even with proper corrections Dr. Grulee and his co-workers may be able to prove statistically what most of us would like to believe—that morbidity and mortality are lowest in breast-fed babies and highest in bottle-fed infants. But in the presence of such statistical errors as I have indicated, the case cannot be considered proved.

JULIUS LEVY, M.D., Newark, N. J.

Director, Division of Child Hygiene, City
of Newark Department of Health.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

SENSITIZATION TO NEOARSPHENAMINE

To the Editor:—Please outline for me a treatment for a woman about 27 years of age who has had a severe cough and bloody sputum for two years. About one year ago I made a diagnosis of bronchial spirochetosis and advised the doctor who had her in charge to give her neoarsphenamine. He did this and after four or five doses she developed a marked dermatitis. I then suggested to him that he give her a saturated solution of potassium iodide after the dermatitis subsided. Then another dose of neoarsphenamine was given in a 10 per cent solution of sodium thiosulphate. The dermatitis immediately returned. She has a good appetite but continues to lose weight and continues to have a productive cough with occasional bloody sputum. Please advise treatment. Please omit name when publishing.

M.D., Texas.

ANSWER.—Most of the articles on bronchopulmonary spirochetosis dismiss treatment by reference to the great efficacy of arsphenamine or its modifications. There are a few reports, however, of cases in which arsphenamine derivatives failed to give satisfaction or, as in the case cited, were out of the question because of sensitization of the patient. The prognosis of chronic spirochetosis is not good. Harper (in discussion of Davis, D., and Harper, E. C.: *Acute Pneumonitis Due to Infection by Vincent's Organisms, Virginia M. Monthly* 58: 95 [May] 1931) quotes Castellani, the originator of modern interest in this disease, to the effect that cases of bronchopulmonary spirochetosis of more than six months' standing cannot be cured.

In any mild sensitization to neoarsphenamine it is justifiable to try minute doses of other arsphenamine derivatives, sulpharsphenamine or silver arsphenamine for example. Sometimes they will prove helpful. In most cases, however, the patient will react unfavorably to them also.

Inorganic forms of arsenic may be used. Castellani recommends solution of potassium arsenite by mouth or sodium cacodylate subcutaneously. Recently trivalent organic arsenic in the form of acetarsone (stovarsol) or the methenamine derivative of meta-amino-para-oxyphenol-arsenic acid has proved of great value in syphilis and might be helpful in this case if tolerated by the patient. One fourth of a 0.25 Gm. tablet might be given and, if there is no untoward reaction, a full tablet. If that was well borne, the regular plan of treatment could be tried, one tablet the first day, two the second, and three the third day, the dosage for the entire day being given at once on an empty stomach. This is sufficient for one week, to be repeated each week for eight weeks. Before the treatment is begun, an examination of the eyegrounds and the visual fields, as is the rule for trypanamide, is recommended. The other precautions, frequent examination of the urine for casts and albumin and careful supervision of the general condition of the patient, must be observed.

Many other drugs have been used with more or less success. A bismuth compound alone or as an adjuvant to the arsphenamines has been given favorable mention; antimony and potassium tartrate was recommended by Castellani; emetine has been helpful in a number of cases.

From Argentina comes a report (Denis, R.; Bares, F. J., and Araóz, J. D.: *Chloroform Therapy of Bronchial Spirochetosis of Castellani, Prensa méd. argent.* 20:2005 [Sept. 20] 1933) of a case resistant to many forms of therapy which yielded to chloroform inhalation as for anesthesia. The first dose was 10 Gm. given in twenty-five minutes. The second

attempt a week later was a failure, because of spasm of the larynx. On the third attempt, seventeen days after the first, 5 Gm. of chloroform was given in thirty minutes and three more such doses were then administered at intervals of three days. Following the last treatment the spirochetes disappeared from the sputum and had not returned at the last examination five months later.

With any form of treatment, the possibility of a double infection with tuberculosis must be kept in mind, sometimes the spirochetosis engrafted on an old tuberculous infection, sometimes the reverse. After apparent cure, the cases should be kept under observation for a long time, as recurrence is common.

INCUBATION PERIOD IN RABIES

To the Editor—In your answer to the inquiry in *THE JOURNAL*, July 21, on the incubation period of rabies in dogs, I notice that you say "The average period of incubation of rabies in the dog is said to be from twenty one to forty days." I have been instructed by the director of the hygienic laboratory with which I am associated to observe carefully for ten days any dog that has caused an abrasion on the skin of any person, and if at the end of ten days the dog is in good health I can reassure the person that there is no danger of rabies developing from the abrasion. It is understood that the abrasion may be from the teeth or claws. The answer seems inconsistent with the advice I have obtained and the same advice I have given my patients. I have been observing this rule for a number of years and have not had any patient develop hydrophobia. Please omit name.

M.D., South Carolina.

ANSWER.—In the statement above no account is taken of the time when the dog himself was bitten and might have been infected. Obviously the incubation period is the time from infection until definite symptoms of rabies appear. Ten days or so after a suspected dog has bitten a human being does not under any circumstances constitute the incubation of rabies in the dog.

Rosenau (*Preventive Medicine and Hygiene*, New York and London, D. Appleton & Co., 1916, p. 40) states that in general the period of incubation of rabies varies from fourteen days to a year or more and gives the average period as follows: "man, 40 days; dogs, 21 to 40 days; horses, 28 to 56 days; cows, 28 to 56 days; pigs, 14 to 21 days; goats and sheep, 21 to 28 days; birds, 14 to 40 days."

Veranus A. Moore (*The Pathology and Differential Diagnosis of Infectious Diseases of Animals*, New York, Macmillan Company, 1916, p. 390) makes almost the same statement as Rosenau and credits the information to Ravenel. Moore also gives the following table of the period of incubation in 144 cases of rabies in the dog as determined by Peuch:

Period of Incubation of Rabies in the Dog

Number of Days of Incubation	Number of Cases	Per Cent
5 to 10..	3	2.08
10 to 15	8	5.55
15 to 20	13	9.03
20 to 25	25	17.36
25 to 30	13	9.03
30 to 35	25	17.36
35 to 40	6	4.17
40 to 45	11	7.64
45 to 50	9	6.25
50 to 55	4	2.78
55 to 60	2	1.39
60 to 65	7	4.86
65 to 70	1	.69
70 to 75	5	3.47
80 to 90	7	4.86
100 to 120..	1	.69
Total ..	144	

Kolmer (*A Practical Text-Book of Infection, Immunity and Biologic Therapy*, Philadelphia & London, W. B. Saunders Company, 1934, p. 785) quotes Reichel (*American Veterinary Review*, January 1911) as giving the incubation period of rabies as follows:

Man, fourteen to ninety days
Dogs, fourteen to sixty days.
Cats, fourteen to sixty days
Cows, fourteen to eighty days.
Horses, twenty one to ninety days
Swine, sheep and goats, twenty one to sixty days.
Birds, fourteen to sixty days.
Rabbits, fourteen to ninety days.
Guinea-pigs, eight to eighty days.

Special attention is directed to the great variation in the incubation of rabies in the dog because of the important rôle of that animal in human rabies. Variation in the incubation of rabies in general may depend on the site and character of the wound, on the amount and virulence of the virus introduced, and on other factors. Bites about the face and fingers are more dangerous than bites in the back and lower extremities, and deep, lacerated wounds are always more dangerous than the superficial.

TANNIC ACID IN BURNS

To the Editor—Please give me your opinion of the use of tannic acid in burns. Would it be safe and proper to use it in solution in case of burns? Tell me what you can as to its use and the best way to use it. Please omit name.

M.D., Iowa.

ANSWER.—Since Davidson in 1925 introduced tannic acid as a therapeutic measure in the treatment of burns, it has been generally accepted as the best method of treating the wound if the patient is seen within the first forty-eight or seventy-two hours after the injury.

Following the infliction of a burn, the patient's general condition should receive first attention. If the patient is in shock, measures to relieve pain, restore external heat and supply fluid should be instituted immediately. If no shock is present or after the patient has responded to treatment, the wound should receive attention. Clothing and débris of various kinds should be carefully removed and loose pieces of tissue carefully lifted off. The surface should then be sprayed with tannic acid solution, which should be freshly prepared. Davidson used a 25 per cent aqueous solution, but most surgeons now believe that a 5 per cent aqueous solution is the most satisfactory. Modification of the solution so that it is neutral or slightly alkaline has certain advantages. Twenty-five grams of tannic acid and 4 Gm. of sodium carbonate added to 500 cc. of water will give a neutral 5 per cent solution. The spraying should be done every fifteen minutes until a firm mahogany-brown membrane is formed. Usually this occurs in about twelve or eighteen hours. If wet dressings are used they should be saturated at regular intervals with tannic acid solution, and a small window can be cut through the dressing to determine whether or not tanning has taken place. When tanning is completed, the dressing can be removed. In very extensive burns the patient may be immersed in a tub containing tannic acid solution. When this method of treatment is used the clothing can be removed after immersion and the solution should be changed as often as necessary to keep it clean. After the area is thoroughly tanned, no dressing is necessary over the burned area. The margins of the wound should be carefully watched and any blebs that form should be opened and painted with an antiseptic solution. A warm air blower should be used over the entire area at four hourly intervals for several days after tanning in order to keep the crust thoroughly dry. It is not necessary to use a blower if the patient is kept under an electric light cradle and the temperature of the air under the cradle is maintained at about 100 F. If after four or five days symptoms of infection appear, the tanned membrane should be carefully inspected and any fluctuant or soft areas should be incised. If infection is present, wet dressings of 5 per cent sodium bicarbonate should be applied over the crust after removal of all the loose membrane over the infected areas. Wet dressings facilitate removal of the crust. If no infection is present, the crust can be allowed to remain until it gradually curls off the healing surface.

This method has the advantage of relieving pain and preventing loss of fluid from the body. The crust acts as an impervious membrane, which prevents contamination of the wound and facilitates the easy handling of patients. Tissues that are destroyed by heat are fixed in the tanning process and in this way rendered inert.

INDUSTRIAL HAZARDS IN WATER SOFTENER MANUFACTURE

To the Editor—I have a patient who is employed by a railroad in its water softening plant, which position he has held for eleven years. During the past two years he has developed a bronchitis and becomes at times asthmatic. A cardiac, renal or tuberculosis origin has been ruled out. He handles large amounts of lime, soda ash and sodium aluminate and breathes a great deal of the dust. There is no system of ventilation or any kind of protection for the men in this plant and I feel sure that his bronchitis is occupational. Kindly answer the following questions: 1. Is there any kind of a mask that can be worn for protection? 2. Is there a state law requiring ventilation of a water softening plant? 3. What is the recognized treatment of these chronic bronchitis cases due to inhalation of lime dust? Please omit name.

M.D., Illinois.

ANSWER.—Water softening with soda ash, lime and similar materials is an intermittent operation involving trivial exposure to dusts compared with such work as the manufacture of lime or soda ash. Both of these dusts are irritants, but extensive observations as to the causation of a pneumoconiosis from their action has established practically no evidence of increased fibrosis from soda ash and from lime or limestone only when the exposure has been gross and prolonged. A roentgen examination will establish the presence or absence of excessive amounts of pulmonary fibrosis such as may result from the action of some dusts. An occupational bronchitis is a possi-

bility, but exact proof can be established only with difficulty. Previous employments in dusty trades may have some bearing on the present condition. As to the specific questions appearing in the query:

1. Yes. A number of respirators are available, such as for one example the Willson No. 3 bag type.

2. No state is known to possess a law peculiarly directed to water softeners, but most states have blanket provisions requiring the rectification of any serious hazard in industry.

3. Apart from the usual treatment of bronchitis, the only special feature connected with an occupational bronchitis is the prevention of further exposure. It may prove to be necessary to remove this worker to other forms of employment, though the wearing of a respirator may suffice.

TREATMENT OF GONORRHEA IN WOMEN

To the Editor:—Can you give me any concrete information on the use of concentrated fat free milk and "manganese butyrate with benzyl alcohol 0.6 per cent" in chronic gonorrhea in the female? Please omit name and address.

M.D., Wisconsin.

ANSWER.—Injections of milk for the treatment of chronic gonorrhea in women have been used for a number of years by many gynecologists. Practically all who use this form of therapy have found it helpful. The injections produce a leukocytosis and build up the patient's general resistance. The pain and tenderness usually associated with chronic gonorrhea are quickly relieved and the inflammatory processes rapidly diminish. In some instances, operations are made unnecessary because of the milk injections. If milk is administered before operation, the latter is simplified in a fair proportion of cases. Furthermore, these injections permit more conservatism when an operation is necessary. The injections are given intramuscularly, and fresh sterilized milk is as good as commercial preparations, if not better. It is best to give only 3 cc. at the initial dose, then increase to 5 cc. and finally to 10 cc. These injections should be given twice a week until exudates diminish in size, pain and tenderness subside, and the patient's general health has improved. There is rarely any untoward reaction from the injections either locally or generally. More information on milk injections in chronic gonorrhea may be found in the following articles:

Gellhorn, George: Milk Injections for Pelvic Infections in Women, *New Orleans M. & S. J.* 78: 557 (March) 1926.

Watkins, R. E.: Milk Injections in the Treatment of Pelvic Inflammatory Disease, *Northwest Med.* 28: 70 (Feb.) 1929.

Greene, E. H.: The Effects of Milk Injections in Chronic Pelvic Inflammatory Disease, *South. M. J.* 26: 443 (May) 1933.

Manganese butyrate is rarely used for therapeutic purposes. No one has reported on its use in chronic gonorrhea in women and, judging from the present knowledge of this substance, it should not be employed as a medical remedy. It does not stand accepted by the Council on Pharmacy and Chemistry.

ALOPECIA AREATA

To the Editor:—I wish to submit this case for your consideration: I have been treating a girl, aged 11 years, for four months for alopecia areata. Her hair has been falling out over a period of fourteen months. She has had treatment for seven months, consisting of ultraviolet exposure once weekly. Additional treatment consisted of thyroid gland tabloid, one tenth grain, four to six daily for one month. Vitamin pearls, three daily for five months, applications of cantharides, olive oil, mange cure, and marrow oil to the scalp have had no appreciable result. The girl is 64 inches (162.6 cm.) tall, weighs 123 pounds (56 Kg.) and has perfect teeth, a clear skin and good health. Her menstrual period began at the age of 10 years 6 months. The hair comes in but does not grow strong and falls out. She has had three growths of hair to date. "Euresol" has been suggested.

H. L. RUDERMAN, M.D., Brooklyn.

ANSWER.—It is difficult to evaluate results of treatment of alopecia areata because of the great variability of the course of the disease, as well as of the response or lack of response of individual cases to various means of treatment. A case may defy all known methods of management and then, apparently spontaneously, clear up quite suddenly.

Because of the not infrequent association between a patchy alopecia and syphilis, either acquired or congenital, the possibility of this patient being syphilitic should be ruled out. If this is done and examination of the affected areas shows no scarring or atrophy such as might follow certain of the alopecia producing dermatoses and the extent of the involvement is not too great, the ultimate prognosis with the type of treatment used so far would probably be good. The youth of the patient, the fact that there has been new growth several times even though not strong or permanent, and the fact that the disease has been present only slightly over a year all point in this direction.

The general symptomatic and tonic treatment is important and this seems to have been well taken care of in this case. If the patient is particularly depressed or self conscious as a result of the affliction, attempts should be made to cheer her, which, as the prognosis is relatively good, seems justified.

Local stimulating preparations are usually indicated. There is a great variety of these and several have already been used in this case. Tricresol in 50 to 100 per cent strength might be applied with caution by the physician, so as to produce slight vesication in the affected areas every two weeks or so. Combined with this, a 5 per cent sulphur ointment might be used over the scalp in general one night a week, the hair being washed the next morning, and a lotion applied with a medicine dropper three times a week between applications of the ointment. The lotion might contain resorcinol monoacetate and castor oil in the following proportions: castor oil 4 cc., resorcin monoacetate 8 cc., spirit of formic acid 30 cc., and sufficient 90 per cent alcohol to make 240 cc.

PROPHYLAXIS AGAINST REPEATED PNEUMONIA

To the Editor:—A boy, aged 13, has had pneumonia five times. The physician who treated the first four attacks is not living. The last attack was treated by me last winter. In the last attack, which terminated in ten days by rather rapid lysis, only the left lower lobe was involved. The last attack was much more severe than others. The temperature ranged from 105 to 106.6 F. for five days. The boy's weight is normal; he is very active and is not fat. He is not a "delicate" child but very light complexioned and is no more prone to other diseases than other children. The tonsils are out. The throat and nose are in good condition. There is no chronic disease of the upper respiratory tract. The tuberculin test is negative. Chest roentgenograms taken several years ago are negative. The attacks always start with coryza and pharyngitis. The patient is always put to bed when he has a cold. Pneumonia develops while he is in bed treating the cold. He gets cod liver oil every fall, winter and spring, and fresh fruits daily. Possibly he does not eat sufficient meat; otherwise the diet is well balanced. Hygiene of the home is beyond reproach. His home is steam heated. The boy is always well dressed for winter weather. Cold vaccines were tried by the former physician and no results were noted. He was advised by the former physician that he would probably "outgrow" the susceptibility to pneumonia. The patient raised no sputum during the last attack. There is no history of sputum culture in the former attacks. Do you advise trying stock prophylactic vaccines in such cases? Please omit name and town.

M.D., North Carolina.

ANSWER.—An attempt should be made to immunize this patient. However, it should be borne in mind that certain individuals are refractory toward active immunization against pneumococcal infection. Insufficient knowledge of the relative activity of the various vaccines makes it impossible to advise any one kind. The important point is the study of the blood of the patient before and two weeks after the use of the vaccine to prove its effectiveness. The mouse protection test is the most sensitive. If antibodies are found in the blood, it would be advisable to vaccinate the boy every six months in the hope of finally producing a state of resistance that will reduce his apparent hypersusceptibility to pneumococcal infection. The important issue is the use of a vaccine that actually stimulates antibody production in the patient.

GRÄFENBURG RING FOR CONTRACEPTION

To the Editor:—I have been hearing rumors about an intra-uterine contraceptive device that was developed in Germany and bears the title of Gräfenburg ring. I understand that it is inserted into the uterine cavity and that it is highly efficient. I should like to find out more about this ring, the dangers that might attend its use, and any other contraindications. Of course any operation that demands dilation of the cervix and the introduction of a foreign body into the uterus always is dangerous because of the possibility of infection. What is the danger of a malignant condition developing? Is there any danger of sterility following the use of the ring for several years if a young woman uses it and then decides that she wishes to have a child? Please omit name and locality.

M.D., Hawaii.

ANSWER.—The Gräfenburg ring has been in use in Germany for several years and considerable data are available concerning its usefulness as a contraceptive device, as well as the dangers and the failures following its use.

Three types of ring have been utilized: a star of silkworm gut, a circle of silkworm gut, and a spiral silver ring. The ring is inserted into the uterine cavity after dilation of the cervix to number 5 or 6 Hegar, and the location of the ring is checked up from time to time by means of roentgen examination. Bleeding or pain necessitates its removal, which is more difficult than introduction. On the other hand, the ring may slip out accidentally or may become displaced. Pregnancy occurs rarely, and ectopic pregnancy is in no way prevented by the ring. According to Robert Meyer, who examined the endometrium in fifteen patients who wore the ring one year or

longer, no inflammatory change is caused by the presence of the ring.

Stefko and Lourié have shown that, when pregnancy occurs with the ring in the uterus, damage to the embryo occurs, resulting in deformed children. Leunbach of Copenhagen at first reported favorably on the use of the silver Grafenburg ring but in 1930 withdrew his endorsement; in 12 per cent of his patients, bleeding and pain required removal of the ring.

Grafenburg had ninety-nine had results in 1,081 cases, but these were less in the case of the silver ring than when silk-worm gut was used. There were thirty-one pregnancies in his series, four of which occurred when the ring was in the uterus and twenty-seven when the ring was lost. Inflammation resulted in seventeen cases. Replacements had to be made in 408 cases from one to eight times—a total of 1,390 replacements. No mention is made in the literature of malignant changes resulting from the use of these intra-uterine devices. In cases in which inflammation occurs, one would expect sterility as a sequel. For a complete discussion of contraceptive devices, including the Grafenburg ring, the correspondent is referred to Dickinson and Bryant's book "Control of Conception," Baltimore, Williams and Wilkins, 1931.

TUCKER'S ASTHMA SPECIFIC

To the Editor—I was called recently to see a patient who had been taking Dr. Tucker's Asthma Specific for asthma and hay fever. She had been using it almost continuously since about August 20, when her first symptoms were noticeable. When I was called she was in a state of unconsciousness, the pulse was weak and thready and she was in profound dyspnea. In spite of stimulation her condition gradually became worse and she died in less than two hours. At the time I was called, the bottle with the label could not be found; but it has now been found and it is labeled as containing 5 grains of cocaine to the ounce. I am strongly of the opinion that the continuous and prolonged use of such a strong solution of cocaine was a very important factor in the sudden heart symptoms, for the patient had at least not had enough trouble with her heart to cause her to consult a physician for it. Please give me your opinion with regard to this phase of this so called asthma specific.

J. M. STEVENSON, M.D., Brooksville, Ky

ANSWER.—The data submitted are insufficient to pronounce the case reported as one of cocaine poisoning, though the possibility of this must be entertained. Discussions of this notorious nostrum may be found in *THE JOURNAL*, May 20 and Sept. 29, 1911, and Nov. 1, 1924. As *THE JOURNAL* has pointed out at various times in the past, the sale of this product violates both the Harrison Narcotic Act and the federal Food and Drugs Act. The manufacturers have claimed that, although the original product contains 5 grains of cocaine to the ounce, the stuff is kept in stock long enough to cause the other ingredients to hydrolyze the cocaine, with the result that when the stuff reaches the consumer most of the cocaine has disappeared—as such. The label, therefore, deliberately falsifies its composition, which should bring it within the purview of the federal Food and Drugs Act. Even if it contains no cocaine, it must obviously contain a derivative of cocaine, so that by its method of sale it violates the Harrison Narcotic Act.

LICHEN PLANUS IN AGED

To the Editor.—A man, aged 72, has a skin condition affecting his ankles particularly but at times his arms and back, which I have diagnosed as a hypertrophic lichen planus. I think there is no question as to the diagnosis, but all forms of treatment that I have tried have failed to give anything except temporary relief. I have used mercuric succinimide and mercuric salicylate in one eighth to one-third grain (0.008 to 0.02 Gm) doses intramuscularly twice weekly for three months. He has been given arsenic intramuscularly and orally. Locally I have used tar and also mercury ointments. I have applied full dosages of ultraviolet rays and of x-rays several times. There was marked temporary improvement at first following the use of all these measures but the eruption returns quickly in a few hours, sometimes with an extensive bright red papular eruption extending half way to the knees. The subjective symptoms are burning and gnawing. There is no itching. During the acute exacerbations there is some secretion of clear watery fluid from small vesicles, which form on the papules. When the condition is more quiescent it involves only the skin on the front and sides of the ankles proper. The affected skin is thickened and has a blue-violaceous color. Small white striae can be seen on the surface. The patient is becoming quite nervous about the condition. I have treated him for the past year with no apparent progress. Please advise as to present methods of treatment of this disease and your opinion as to how best to handle this particular case at this time. Would neocarsphenamine injections be of any probable value?

M.D., Kan.

ANSWER.—There is some question as to the diagnosis in this case. While the violaceous color and the chronicity suggest lichen planus, the acute exacerbations with vesiculation are not typical for that disease. They suggest rather some form of chronic eczema or perhaps lichen simplex.

The treatment of hypertrophic lichen planus is very difficult and at 72 years of age can easily be hopeless as to cure. Local treatment to reduce the burning sensation would seem to be indicated. The tars, menthol and phenol are the most useful of the standard drugs. Tars may cause furuncles if kept up too long. Phenol should not be used in strength greater than 1 per cent in ointments for fear of phenol gangrene. Camphor, menthol and chloral, from 5 to 20 per cent of each, can be used in alcohol as an anesthetic lotion.

Arsphenamine or neocarsphenamine is not particularly helpful in lichen planus and not justifiable at 72 years of age without a direct indication.

"HEART WORMS"

To the Editor.—In southern Florida it is conceded by dog owners that a majority of adult dogs are infested with so called heart worms. I have seen at autopsy a heart cavity completely filled with adult worms (in the dog) that measured several inches long. A drop of blood under low power will show from one to twenty larvae that appear one-fourth inch long. They are very motile. Can you tell me what variety these filariae are? Is there any relation to *Filaria bancrofti* or *Filaria sanguinis-hominis*? Can they be transmitted to man? What mosquito transmits them? What is the incidence of *Filaria* infestation in man in southern states? The answer to these questions will be of much interest to local physicians, as we are frequently asked whether man is likely to be infested from this variety found so prevalently in dogs. Please omit name.

M.D., Florida.

ANSWER.—The worms found in the heart are undoubtedly the common heart worm *Dirofilaria immitis*, which is a filarid widely distributed in the warmer countries of the world and which occurs in the dog, cat and various wild carnivores. As it can be transmitted by a number of mosquitoes, it is difficult to name the chief carrier in Florida. The probability is that it is carried chiefly by *Culex fatigans* (quinquefasciatus) and *Culex pipiens*. *Dirofilaria* has never been found in man and there is no connection between it and human filariasis. With the exception of a few sporadic cases, the only endemic center of human filariasis (*Filaria* or *Wuchereria bancrofti*) in the United States is in Charleston, S. C. As far as is known, any human infections in Florida or the neighboring states would probably have originated in the Charleston area.

INNERVATION OF DENTAL PULP

To the Editor—I wish to direct your attention to an error in a portion of the answer to the inquiry concerning the innervation of the dental pulp appearing in *Queries and Minor Notes* in *THE JOURNAL*, October 6, page 1092. From the author's statement it might be inferred that anesthesia of the third division of the fifth nerve may be obtained by a mandibular block. This is incorrect, as such a procedure would affect only the terminal branches anterior to the point of injection; namely, the inferior dental, lingual and mental branches of this nerve. The fact is that, in order to produce anesthesia of the third or mandibular division of the fifth nerve for surgical or therapeutic purposes, it is necessary to inject the solution near or into the foramen ovale located in the greater wing of the sphenoid bone where the nerve emerges from the cranial cavity.

This particular inquiry touches on a problem that puts to test the erudition and skill of the ablest operators from time to time. A much deeper anesthesia is needed and is often more difficult to obtain for pulp extirpation than for other even more extensive surgical treatment. This is especially true in patients of middle age, particularly when the two upper bicuspid and first molar teeth are involved. In these cases failure is due entirely to the inability of the anesthetic solution to pass through the dense and thick anterior cortical plate of the superior maxillary bone, under the surface of which is located the middle superior dental (alveolar) nerve, which innervates these teeth. In this type of case other methods must be employed to obtain anesthesia, and an intraosseous block is one that gives satisfactory results. In certain other cases, when the pulp is already exposed, pressure anesthesia with procaine hydrochloride may be employed with equally good results.

EMIL L. AISON, D.D.S., Chicago.

ELECTROCARDIOGRAPHY IN PRACTICE

To the Editor.—Under *Queries and Minor Notes* in *THE JOURNAL*, September 29, you advised "M.D., Massachusetts," to install an electrocardiograph in the hospital in question and to charge a small fee for interpretation of each tracing, reimbursement for the investment to be dependent on a large volume of business. In your reply, I believe, you should have considered the cardiologist in the neighboring city who has invested in a similar machine and whose volume of business cannot be comparable with a hospital of 125 patients daily census. This cardiologist has had to spend considerable time and money for the knowledge to interpret such tracings. I believe that hospitals should not compete by reducing fees because of a greater volume of business available but should charge prevailing rates of private physicians in the community so as to avoid unfair competition. Emphasis should be made on the interpretation of the tracing rather than the mechanical factor. I hope this will be accepted as constructive criticism.

EMIL J. SUSSLIN, M.D., Bridgeport, Conn.

Illinois June Examinations

Mr Eugene R Schwartz, superintendent of registration, Illinois Department of Registration and Education, reports the written and practical examination held in Chicago, June 26-30, 1934. The examination covered 10 subjects and included 100 questions. An average of 75 per cent was required to pass. Two hundred and twenty-three candidates were examined, 218 of whom passed and 5 failed. The following schools were represented:

School	PASSED	Year Grad	Per Cent
Chicago Medical School	(1933) 77, (1934) 75, 76, 77, 77, 77, 78, 79, 79, 79, 80, 81, 81, 82, 82, 82, 83, 83, 84, 84, 86, 87	(1931)	75,*
Loyola University School of Medicine	77, 80, 80, 81, 81, 81, 81, 82, 82, 82, 82, 82, 82, 82, 83, 83, 83, 84,* 84, 84, 84, 84, 85,* 85, 85, 85, 85, 85, 85, 85, 85, 87, 88	(1934)	76,

Northwestern University Medical School	(1932)	81,
(1933) 81,* 83,* 85, 87, 88, 88, (1934) 81, 81, 81, 81, 81, 82,* 82, 83,* 83, 83, 84, 84, 84, 85, 86,* 86, 86, 88, 88

Book Notices

Atlas Fundus Oculi. By William Holland Wilmer, M.D., LL.D., Sc.D., Professor of Ophthalmology and Director of the Department of Ophthalmology of the Johns Hopkins University School of Medicine. Introduction by Warfield T. Longcope, M.D., Professor of Medicine and Director of the Department of Medicine of the Johns Hopkins School of Medicine. Cloth. Price, \$35. Pp. 39, with 100 colored plates. New York: Macmillan Company, 1934.

The library of every student of ophthalmology should contain a copy of this work. Indeed, every one who uses the ophthalmoscope even occasionally can hardly fail to derive the utmost satisfaction from the color plates, which Annette S. Burgess has spent four years in producing. The first twenty depict normal animal and human fundi with the more frequently encountered congenital human anomalies. The last eighty set forth the pathologic changes of the human eye in most graphic fashion, from primary optic atrophy to bilateral metastatic carcinoma of the choroid before and after the use of radium. Concise but comprehensive descriptions, with brief histories, accompany each plate. Following the introductory pages the author presents an excellent monograph on ophthalmoscopic examination with valuable suggestions for the interpretation of color variations as regards race and complexion in optic nerve and retinal vessel changes. With the concluding words of Warfield T. Longcope's introduction, the book "may be regarded as a series of personal records selected with discretion and wisdom that comes with great experience, to illustrate the appearance of the fundus under normal conditions and in a great variety of pathological states. . . . It unfolds before our eyes one beautiful reproduction after another, each one of which depicts the changes of the fundus with a brilliancy and accuracy that cannot be surpassed." The work is a classic in the literature of modern ophthalmology.

La séro réaction blennorrhagique. Par Bertrand Rème. Paper. Price, 30 francs. Pp. 179. Paris: Masson & Cie, 1934.

This is a comprehensive review of the work on the complement fixation test in gonorrheal infections from 1906 to 1934. It contains abstracts from more than 300 papers published on this subject, only twenty of which were in French. Starting with the history of the test, Rème gives an exhaustive review of the technic, the serologic interpretations and the specificity of the reaction and ends with its practical value. After correlating the work done by the various authors, Rème concludes that, while more research work should be done on the complement fixation test, the test is reliable and of great value both as a diagnostic agent and in determining the question of cure. He deplores the fact that the test is so little understood and used by the medical profession. He also feels that where the test has proved unreliable the fault lies in the use of improperly prepared antigens and in faulty technic in standardizing the various reagents used in making the test. The book is written in simple French, and all persons interested in the complement fixation test in gonorrheal infections should obtain a copy.

The Elements of Experimental Embryology. By Julian S. Huxley, M.A., Honorary Lecturer in Experimental Zoology, King's College, London, and G. R. De Beer, M.A., D.Sc., Jenkinson Lecturer in Embryology, Oxford. Cloth. Price, \$7. Pp. 514, with 221 illustrations. New York: Macmillan Company; Cambridge: University Press, 1934.

The need of new concepts capable of compassing the facts of natural science—in chemistry, in physics, and especially in biology—is generally recognized and increasingly insistent. In this book these eminent English thinkers seek to formulate as far as may be at present general rules and laws that are recognizable in one small field of biology; namely, the earlier stages of embryologic development. They limit their consideration to the biology of differentiation; that is, "the production of an organized whole with differentiated parts out of an entirely or relatively undifferentiated portion of living matter." Amphibian development is selected to exemplify the phenomena from which the principles are deduced. The development is followed descriptively and experimentally in these animals through the stages of beginning differentiation—through the earliest appearance of polarity, symmetry, gradient fields, special local fields, and so on. The attempts at explanation heretofore offered are briefly sketched: preformation, determinants, par-

ticulate inheritance, the "soul" of Aristotle and the "entelechy" of Drisch, and their inadequacy is shown. The new principles suggested substitute for the verbalism and vitalism of these older theories the "organizers" of Spemann and the "gradient fields" developed mainly by Child. The authors do not offer this formulation as a complete explanation. They hope only to give a "first degree of scientific explanation of the facts." As such it will be welcomed by all who realize the need for synthesis of new concepts in natural philosophy. A brief final chapter is devoted to a summary of the principles deduced, and a penultimate chapter is devoted to a consideration of the prefunctional period of development as contrasted with the functional period. The excellent index will be of great help to the student, who will find in this book one of the best reviews of a subject to which experimental embryology has made enormous additions in recent years and which is of prime importance in biologic philosophy. The book is dedicated to two great experimental embryologists, Spemann of Freiburg and Harrison of Yale.

Essentials of Infant Feeding and Paediatric Practice. By Henry P. Wright, B.A., M.D. Cloth. Price, \$4.25. Pp. 212. London & New York: Oxford University Press, 1934.

In the small book the author presents modern teaching in a terse, practical manner "for the benefit of the trained nurse, the student of medicine and the general practitioner." He repeatedly refers to the work of numerous authorities. The first section (sixty-two pages) is devoted to general topics, as growth and development, physiology, hygiene, breast feeding, artificial feeding and stools in infancy. The second section (sixty-seven pages) deals with disturbances of nutrition, including failures to gain weight, vomiting, diarrhea, constipation, prematurity, rickets, tetany and scurvy. The third section (sixty-three pages) gives information on preventive measures, serums, isolation rules, diets, therapy, transfusion and laboratory tests. The book should appeal to "the student of medicine in a crowded curriculum, and the general practitioner in a strenuous life." In some places the text is too greatly abridged; in others there is rambling. In some respects the author is ultraconservative; in others relatively new measures and procedures are recommended. Under pyloric stenosis, for example, only surgery is mentioned as therapy. On page 148 one reads: "Add this to a pint (20 oz.)" (a pint is 16 ounces in the United States). Regarding scarlet fever antitoxin, he says: "Many firms have withdrawn their products from the market." His dosage of convalescent poliomyelitis serum is not adequate. No mention is made of enteritis, although bacillary dysentery and rules for its prevention are briefly discussed. The chief field of usefulness of this book will be as a work of handy reference.

Pubertad: Diario de una colegiala. Traducción directa del original francés por Paul Martín. Paper. Price, 5 pesetas. Pp. 246. Madrid: Javier Morata, 1934.

This is a psychoanalytic study of a diary written by a girl during the age of puberty. The behavior of girls toward persons of the opposite sex, their emotional reactions and their interpretation of love and nature, with vivid colors, as well as the instability of their character and love and other acts are explained by the development and evolution of love at that age. The book is of value for teachers and psychologists in understanding many details of the character and emotions of girls at this age.

The Twilight of Parenthood. By Enid Charles, M.A., Ph.D. Cloth. Price, \$2.50. Pp. 226, with 7 illustrations. New York: W. W. Norton & Company, Inc., 1934.

The point of view of the book is stated to be that: "When prosperous classes of industrial nations, like other ruling castes in the past, have become the victims of their own ideology. In seeking to mitigate poverty by preventing the poor from reproducing, they have molded the destiny of a civilization which has lost the power to reproduce itself." Scientific and technical progress has disproved the Malthusian theory, but the growth of population is being restricted until the world is now faced with the "menace of underpopulation." The development of new mathematical technic in the field of vital statistics has shown that within each industrial era population tends to

follow a logistic curve approaching stability. Such an upper limit is not definitely fixed, since social changes may start a new curve from the upper limit of the present one. "The conclusion which emerges most clearly from our study is that the *laissez faire* economy is a biologically self-destructive arrangement of man's social life."

Medicolegal

Workmen's Compensation Acts: Refusal to Submit to Operation.—In the course of his employment, May 9, 1927, Gidley fractured a semilunar cartilage in his right knee joint. Permanent partial loss of use of the leg followed. He first sued his employer, under the Federal Employers' Liability Act, on the theory that at the time of the injury both he and the employer were engaged in interstate commerce. In 1931 the Supreme Court of Illinois held that the parties were engaged not in interstate commerce but in intrastate commerce, and the suit was dismissed. In the meantime Gidley protected his rights under the workmen's compensation act of Illinois by filing, May 9, 1928, with the industrial commission, a petition for compensation. No hearing was held on this petition until 1932, when an arbitrator awarded compensation based on 130 weeks temporary total disability and a 35 per cent total permanent loss of use of the right leg. The industrial commission affirmed the award with respect to the permanent loss of use but determined that the temporary total disability extended only for twenty-nine weeks and two days. The superior court, Cook County, however, affirmed the award as made by the arbitrator. The employer thereupon appealed to the Supreme Court of Illinois, which affirmed the judgment of the superior court, sustaining the arbitrator's award.

The employer contended that the limitation by the industrial commission of the duration of compensable temporary total disability was correct, asserting that the total disability in excess of twenty-nine weeks and two days was due to the workman's refusal to submit to an operation. All the medical witnesses, said the Supreme Court, agreed that the temporary total disability of 130 weeks was due to the fracture of the semilunar cartilage and that there is a feasible operation for the cure of that condition. They disagreed, however, as to the advisability of such an operation and the danger involved in it. Three physicians, testifying for the workman, believed that there was danger of an infection, which might have resulted in a permanently stiff knee. Only the medical witness testifying for the defendant seemed to belittle the danger. Furthermore, continued the court, the offer or demand by the employer that the workman submit to an operation was made, according to the evidence, Nov. 20, 1927, when there was nothing in the case pending before the industrial commission. Neither the employer nor the workman had then made application for adjustment of compensation. Consequently the employer had at that time no statutory authority to make the demand, nor was it the statutory duty of the workman to submit. It is for the industrial commission, not the employer, to determine whether or not an injured workman may be required to submit to an operation, but at that time not even the industrial commission could have entered an order requiring him to do so.

The only question of law involved, said the court, is whether the workman's conduct was so arbitrary and unreasonable that his continued disability can be said to have resulted from his own misconduct rather than from the original injury. On this issue, the employer had the burden of proof and all doubts must be resolved in favor of the workman. There was evidence that the workman, in refusing the operation, acted on the advice of his physicians. An operation might have cured his knee, but it might have made it much worse. There was no showing of bad faith, and the court could see no more reason for his following the advice of the employer's physicians than the advice of those physicians of his own choice. The court therefore could not say that the workman's conduct was such as to deprive him of his right to compensation.

For the reasons stated, the Supreme Court affirmed the award of the arbitrator.—*Gidley v. Industrial Commission (Ill.)*, 189 N. E. 881.

Malpractice: Negligence Following Tonsillectomy.—The defendant-osteopath, Townsend, arranged for the performance of a tonsillectomy on the plaintiff's son, 8 years old, and undertook the postoperative care of the case. The operation was done by an osteopath from a nearby city, Hartsock, in the defendant's office. After the operation, about 10 o'clock in the morning, the patient remained in the office until 7 o'clock that evening, when he was taken to the home of an uncle, where he remained until he died on the following day. Hemorrhage followed the operation, and Hartsock, before he left the office about 12:30, gave a hypodermic injection, which he said was to coagulate the blood. The bleeding continued and was called to the attention of Townsend, who said it was all right. The patient vomited, however, irregularly, sometimes every hour and a half and sometimes less frequently, and the vomit each time contained red blood. About midnight the plaintiff, the patient's father, summoned the defendant, who administered another hypodermic injection. At 3:30 on the morning following the operation the plaintiff reported to the defendant the patient's condition. The defendant did not come to see the patient but advised the plaintiff to give the patient nourishment and promised to call in the morning. The bleeding continued through the night and was continuing at 8 o'clock the following morning, when the plaintiff went after the defendant and told him that he had better come right away and bring with him some one who knew more than he did. The defendant came, bringing with him his father, a doctor of medicine, who only advised the application of warmth and the giving of nourishment. Thereupon the plaintiff summoned a physician from a nearby town. That physician found the boy weak from loss of blood and still bleeding profusely. He advised the immediate administration of nourishment through the rectum and as soon as the necessary instruments could be procured, and after the arrival of Hartsock, who had operated in the first instance, two or three stitches were taken in the pillars of one tonsil and the hemorrhage stopped. The patient died, however, about 4 o'clock that afternoon.

The patient's father filed suit against the defendant-osteopath, Townsend, and against the nonresident operating osteopath, Hartsock. He was unable to get legal service on Hartsock, and the case therefore proceeded with Townsend as sole defendant. Damages were awarded in favor of the plaintiff and Townsend appealed to the Supreme Court of Kansas. Although the physician who was summoned by the plaintiff testified in his behalf, the defendant apparently sought to have the verdict of the trial court set aside because of the absence of expert testimony to support it. The Supreme Court pointed out, however, that results so pronounced as to be apparent and matters within the common knowledge of mankind may be testified to by any one familiar with the facts.

"It required no doctor to inform the jury," said the Supreme Court, "that when a surgical operation was had upon the throat and thereafter the patient spat up blood, that it was blood. The fact that the boy vomited, the frequency thereof, the testimony of the color, the effect on the child, were facts that any person of ordinary intelligence could discern, and evidently the jury saw fit to believe that the father vainly called the doctor about 3:30 in the morning, and a few hours later, believing the child was not being properly treated, called in another physician, who promptly saw to it that the boy was nourished, and assisted Dr. Hartsock in a second operation which stopped the bleeding. There was also the father's statement that defendant told him the boy died 'of tonsiline hemorrhage.' The plaintiff's evidence also showed that the defendant undertook the care of the boy following the operation; that he permitted the bleeding to continue, the giving of the hypodermic injection at midnight being all that was done to stop it; and that he made no effort to call Dr. Hartsock until the parents had called Dr. Newman. The above recited lay testimony, together with the medical testimony previously referred to, made a prima facie case, prevented a ruling favorable to the defendant on his demurrer, and precluded a directed verdict in his favor."

The judgment of the lower court, in favor of the plaintiff, was therefore affirmed.—*Flentie v. Townsend (Kan.)*, 30 P. (2d) 132.

Radiological Society of North America, Memphis, Tenn., December 3-7. Dr. Donald S. Chiles, 607 Medical Arts Building, Syracuse, N. Y., Secretary.
Society for the Study of Asthma and Allied Conditions, New York, Dec. 8. Dr. W. C. Spain, 116 East 53d Street, New York, Secretary.
Southern Surgical Association, Sea Island, Ga., Dec. 11-13. Dr. Robert L. Payne, 142 York Street, Norfolk, Va., Secretary.
Western Surgical Association, St. Louis, December 7-8. Dr. Albert H. Montgomery, 122 South Michigan Boulevard, Chicago, Secretary.

AMERICAN ASSOCIATION FOR THE STUDY AND CONTROL OF RHEUMATIC DISEASES

Third Conference on Rheumatic Diseases

First Annual Meeting, held at Cleveland, June 11, 1934

The President, DR. ERNEST E. IRONS, Chicago, in the Chair

The New Association and Its Purposes

DR. ERNEST E. IRONS, Chicago: The need for extending the work so well begun by the American committee, and the necessity for better correlation of what is known of arthritis with what is done for the patient, convinced us of the desirability of this association. We hope that this organization will be an association of those interested in obtaining and promulgating a well rounded conception of the problem of the arthritides, so that rational methods of treatment may be available to the physicians in charge of the many thousands of sufferers from arthritis. It is hoped that we may now extend membership so that all parts of this country may be represented and the number of qualified participants in the work increased.

Another activity will be the encouraging of the organization of local groups of those especially interested in the study of arthritis to stimulate individual research and promote general interest in the dissemination of knowledge of the disease and its treatment. In order that these purposes of the association may best be carried out and its discussions made accessible to as large a number of physicians as possible, meetings for the present will continue to be held on the Monday preceding the Scientific Meeting of the American Medical Association. Chronic arthritis is the greatest single cause of disability and suffering in temperate climates. The magnitude of the suffering and disability caused by arthritis offers a major challenge to the medical profession and to the public. Many etiologic factors are operative in the early and later stages of chronic arthritis. While one, such as chronic infection, may be the outstanding cause, the correction of which is sufficient to swing the balance toward recovery, it frequently happens that, in spite of the correction of perhaps this initial cause, other factors continue to be operative and the arthritis progresses. Therefore, classification or a program of treatment of chronic arthritis based on the theory of one or another causative factor must fail in clinical use and a broader view of the disease is required. The division of chronic arthritis into two clinical groups, atrophic and hypertrophic, seems to the American committee to offer the best clinical working classification for the present. The conclusions reached through many of the studies on the relation of one cause, such as infection, to chronic arthritis have been invalidated by failure of observers to take into consideration the natural history of the disease. In chronic arthritis, especially in the atrophic type, periods of spontaneous improvement occur, and conclusions as to etiology or therapy, based on treatment instituted at the beginning of a period of natural improvement, are likely to be misleading.

Chronic arthritis is to be thought of as a disease that affects the body as a whole rather than the joints alone. Each patient presents a special problem, and the employment of one procedure for all patients with a disease whose etiology and course vary

in each case seems unwarranted. One of the chief functions of this association is to furnish a forum in which, through discussion, new ideas may be evaluated and fitted in with what is already known. It is our hope that the work begun by the American committee may be continued through the widened opportunities afforded by this association.

Focal Infection and Arthritis

DR. ARTHUR STEINDLER, Iowa City: Almost 120 years has passed since Benjamin Rush emphasized the effect of dental disease on generalized arthritis, and more than twenty years has passed since Billings (1912) and Rosenow (1915) forcefully directed attention toward the problem of focal infection. Nevertheless there is still an active controversy in which such a relationship between local and systemic disease is challenged, both in principle and in fact. Considering the high incidence of focal disease on one hand, and the great fluctuations in the usual course of systemic disease on the other, it is not strange that this question of relationship should be a most difficult one to settle.

It is not yet known how foci act to produce arthritis. Is a bacteremia produced? Are the joint manifestations actually metastatic lesions or the results of some toxic agent? Is it a question of elective localization, of a special tissue affinity? What are the agencies that determine why some persons are more prone to secondary focal infection? A focus of infection may be relatively harmless to the nonrheumatic individual but serious to the rheumatic one. Therefore the evaluation of focal infection should be considered not just in the light of statistical studies on the incidence of foci but by considering the effect of the combination of a focus and an arthritic diathesis.

Of 4,339 cases of nonspecific arthritis that have been studied, 3,004 were of type 1 (atrophic arthritis), 1,335 were of type 2 (hypertrophic).

Foci of infection were present in 17 per cent (520) of the cases of atrophic arthritis and in 17.7 per cent (240) of those of the hypertrophic type. These figures may be much too low, as many of the ambulatory patients could not be subjected to complete search for foci. In those with focal infection the relative incidences were as follows: The tonsils were believed to be infected in 55 per cent of cases of the atrophic type and in 64 per cent of those of the hypertrophic type, the teeth in 17 per cent of the atrophic and in 23 per cent of the hypertrophic, and the sinuses in 46 per cent of the atrophic and in 57 per cent of the hypertrophic. The biliary or gastro-intestinal tract was believed infected in 1.5 per cent of cases of the atrophic type and in 7 per cent of the hypertrophic, and the genito-urinary tract (including the prostate gland and adnexa) was believed infected in 6 per cent of cases of the atrophic type and in 5 per cent of cases of the hypertrophic type.

The evaluation of the effect of removal of foci is as follows: In the analysis of those cases in which removal of foci was followed either by subsidence or by decided improvement within days or weeks, it was found that 35 per cent of the cases of atrophic arthritis and 20 per cent of the cases of hypertrophic arthritis acted in this manner or gave a "positive response." In children, naturally, the response was better than in adults, but there were few patients less than 10 years of age in this group. These figures would therefore represent the probable upper limit of the percentage for positive response.

Because it was found in some of the cases that improvement did not persist during the time of observation, these cases were eliminated from the former group of cases that did not evince signs of recurrence of symptoms within one year, the remaining cases showing no recurrence. These remaining cases represented 15 per cent of the atrophic type and 8 per cent of the hypertrophic type. The second group, therefore, represents the lower limit of positive responses to the removal of foci.

In other words, the figure for immediate and striking response to the removal of foci for the atrophic type was 35 per cent and for lasting response for this type 15 per cent. The figure for immediate positive response to the removal of foci for the hypertrophic group was 20 per cent and that for lasting response was 8 per cent. It therefore appears that, even on the basis of the lower percentage of lasting and striking response to the removal of foci (15 and 8 per cent, respectively), the systematic policy of removal of established foci of infection in arthritis would be justified.

Treatment of Chronic Atrophic (Rheumatoid) Arthritis with Streptococcus Vaccine on the Basis of Skin Sensitivity

DR. CHARLES W. WAINWRIGHT, Baltimore: The relation of streptococci and streptococcal infection to chronic atrophic arthritis remains in an uncertain position in spite of the many diligent investigations pursued during the past decade. Not only do students of the disease differ about the interpretation of experimental results, but the results themselves lack uniformity. If a relationship exists, it might exist in one of three ways: (1) The joint lesions may be the result of the localization of streptococci circulating in the blood stream, (2) the joint lesions may be due to toxins liberated from some focus of streptococcal infection elsewhere in the body, or (3) the joint reactions may be allergic in nature and represent hypersensitivity of the joint tissues to streptococci, resulting from low grade infections or from the persistence of foci of infection in the body. If the first relation obtains, then the nature of the joint change and the method of its production are easily understood, for it is a metastatic infection that is being dealt with. If the second obtains, then a high degree of specificity is implied; if the third, then an equally high degree of specificity exists, or else one must assume with Clawson and Wetherby that there is a species rather than a strain specificity. If the joint changes are regarded as allergic, it is at times difficult to explain just how the contact of antigen with antibody in the allergic joint comes about.

Although the lack of uniformity in results obtained from blood cultures is striking, the presence of serum agglutinins for hemolytic streptococci in a very large percentage of cases of atrophic arthritis has been reported by numerous observers. It has also been reported that patients suffering from atrophic arthritis exhibit positive skin reactions to killed streptococci and their fractions in a larger percentage than do healthy persons or those suffering from some other disease.

At the Johns Hopkins Hospital we have been unable to duplicate the results of Cecil, Nicholls and Stainsby. Ninety-four blood cultures were made in ninety-one cases of chronic atrophic arthritis. The following organisms were obtained: Streptococcus viridans in one case, and diphtheroids in four cases. In addition, staphylococci were found in four cases and gram-positive bacilli in three cases, all considered contaminations. In fourteen cases, cultures of joint tissue were made: in twelve the cultures were negative, in two cases contaminating mold was encountered. Streptococcus viridans was found once, but not again when the culture was repeated. The serums in forty-six, or 90 per cent, of fifty-one cases were found to possess agglutinins for hemolytic streptococci in dilutions varying between 1:20 and 1:1,280. Tests were made with both living and heat-killed antigens. The extent of the dilution was somewhat lower than that reported by other observers.

All of the fifty-five patients who were tested gave positive skin reactions to one or more strains of streptococci, hemolytic and green, the whole organisms being used. An area of erythema 1 cm. in diameter or larger was considered a positive reaction. In most cases it was larger (from 1 to 5 cm. in diameter). In all cases the reaction was tuberculin-like in appearance. In twenty-four cases the intradermal reactions were to hemolytic streptococci alone, in three to Streptococcus viridans alone and in twenty-eight to both types. In 90 per cent, maximal reactions were to hemolytic streptococci and in 10 per cent to viridans, but no single strain predominated in causing maximal reactions. For reasons stated no series of controls or of patients without arthritis was made. No attempt was made to interpret these results in terms of causation. Twenty-one of twenty-eight patients have shown improvement when given intravenous injections of streptococcus vaccine prepared from the strain to which they were most skin sensitive for periods of from two to more than twelve months.

The presence of agglutinins for hemolytic streptococci in the serums of patients suffering from chronic atrophic arthritis seems well established. A positive reaction does not of necessity indicate a causal relationship between hemolytic streptococci and atrophic arthritis, but it does suggest that streptococci play a rôle in the disease. Agglutination may be due to the presence of natural, not acquired, or specific agglutinins (as

Dawson, Olmstead and Boots suggest) but the frequency with which it occurs in atrophic arthritis is the most incriminating evidence thus far produced against the streptococcus in this disease.

When skin sensitivity to streptococci exists it does not necessarily indicate that there is also joint sensitivity or general sensitivity. The objections raised to the interpretation of skin reactions to autogenous vaccine, namely, that they may indicate varying irritability of the patients' skins, natural toxicity of the bacterial species, or perhaps sensitization to certain bacterial groups, must be considered. However, the effect of subsequent treatment with vaccines on the skin reactions indicates that they do represent a specific skin sensitivity to the strain used. I do not know that the diminution and disappearance of the skin reaction is a measure of desensitization, nor that the increase in the agglutinating power of the patients' serum is a measure of immunity. I do feel, however, that the skin reaction is the most definite evidence of hypersensitiveness obtainable.

DISCUSSION ON PAPERS OF DRS. STEINDLER AND WAINWRIGHT

DR. J. ALBERT KEY, St. Louis: Since it is said that no individual reaches adult life with normal tonsils and with normal teeth, it is unusual to hear that Dr. Steindler found foci in only about 17 per cent of his cases of atrophic and hypertrophic arthritis. It is noteworthy that he found foci of infection as frequently in cases of hypertrophic arthritis as in cases of atrophic arthritis. Few believe that hypertrophic arthritis is a bacterial disease. Only a small percentage of his patients were cured by removal of infected foci. Considering the natural course of the disease, it is known that this many or more get better in spite of anything that is done and under a large variety of forms of treatment from 50 to 60 per cent of patients are improved. With his vaccine Dr. Wainwright improves 75 per cent of his patients. Most physicians use vaccines in arthritis, and I use them myself with the full knowledge that there is no disease of which I can find record that has been proved cured by vaccines. It is all right to give vaccines provided one does not forget to treat the patient and his disease with additional accepted and indicated measures. With regard to cultures of blood and joints I can't confirm anybody's results, even my own. Some years ago I isolated staphylococci and diphtheroids. Sterilizing the skin better, I later failed to get the latter. The habit should be condemned of discarding all staphylococci as contaminants and considering the streptococci found as the cause of whatever disease one is studying. There is no more reason why arthritis should be due to streptococci than to staphylococci or diphtheroids. However, my own experiments convince me that the arthritis produced with streptococci and diphtheroids is more closely akin to human arthritis than that produced in animals with staphylococci.

DR. M. H. DAWSON, New York: Dr. Steindler stated that in considering the significance of infected foci in arthritis it was required to compare the incidence of foci of infection in arthritis with the general incidence of such foci in nonrheumatic diseases, but he failed to give any statistics on this important point. It is most important to distinguish between atrophic (rheumatoid) and hypertrophic (osteo) arthritis. I believe that they are two separate diseases, the latter being due to the degenerative changes of age and in no way being related to infection. The former seems associated in some way with infection. In atrophic arthritis I agree with Dr. Steindler that infected foci, especially in tonsils and sinuses, are of considerable importance and that their removal, especially early in the disease, may give excellent results. I also believe that the gastro-intestinal tract plays only a small rôle in the production of this disease; certainly the significance of its reported abnormalities remains most uncertain. Dental infection, I feel, is related more to nonarticular rheumatism than to atrophic arthritis. It is my experience also that removal of foci does not particularly affect the course of hypertrophic arthritis. Dr. Wainwright's cultural and agglutination studies are in accord with my own. The fact seems established that the serum from the majority of patients with atrophic arthritis possesses the capacity to agglutinate hemolytic streptococci. Furthermore, this agglutinating capacity is not related to the nonspecific agglutinating property exhibited by the serum in many acute febrile diseases. I

recently carried out a "blindfold" agglutination test on a large number of serums from a well known arthritis clinic. The results of this test demonstrated that it was possible to identify the serums of patients with atrophic arthritis in a high proportion of cases. More recently I have extended my agglutination studies to include precipitin tests. Various protein and carbohydrate fractions of *Streptococcus hemolyticus* have been employed. These studies indicate that there is a close approximation between the capacity of serums from patients with atrophic arthritis to agglutinate hemolytic streptococci and to precipitate various fractions of this organism. I do not believe that these immunologic reactions establish the etiology of atrophic arthritis, but, as Dr. Wainwright said, they constitute the most incriminating evidence that has been brought forward against *Streptococcus haemolyticus* in this disease. In my experience, skin reactions in atrophic arthritis are variable and difficult to interpret. In a limited series of observations I was unable to demonstrate any correlation between the degree of skin reactivity to various strains of hemolytic streptococci and the clinical condition of the patient. Furthermore, sufficient evidence has not been brought forward to indicate a relationship between skin reactivity and the reactivity of joint tissues. There is suggestive evidence, however, that patients with atrophic arthritis do, as a group, show a higher degree of skin reactivity to *Streptococcus haemolyticus* than do patients suffering from other diseases. Dr. Wainwright stated that twenty-one of a series of twenty-eight patients treated by the use of intravenous vaccines received definite benefit. However, as he mentioned, there was no control series and the treated patients received the additional benefit of from four to eight weeks' rest in bed. It has been my experience that an equally large proportion of patients show definite improvement on a regimen of adequate rest alone. During the last five years I have used hemolytic streptococcus vaccines on a large series of patients with atrophic arthritis. The methods of administration and the doses employed have been quite comparable to those just reported. The value of this form of therapy remains unproved.

DR. RUSSELL L. CECIL, New York: May I say a word about the bacteriology of atrophic arthritis? The results so far reported can be divided into three groups: (1) the work of those who find streptococci in the blood and joints of patients with atrophic arthritis but not in controls, (2) the group to which Drs. Dawson, Boots and Wainwright belong, who find practically all cultures of blood and joints sterile both in controls and in patients with atrophic arthritis, and (3) the group, represented by Dr. Callow's recent study on rheumatic fever and May Wilson's report on blood cultures in children with rheumatic fever, in which a high percentage of streptococci are found among patients with atrophic arthritis, with rheumatic fever and in controls. This situation shows how confused the whole problem is. If streptococci are only contaminations, one wants to know it. The question is far from solved. I don't think I am misquoting Dr. William H. Park in saying that he believes the streptococci I have isolated have actually been from the blood, but he is very conservative and cautious about interpretation. I recently asked Dr. William Elser to help me on this problem. Dr. G. I. Steffen took the blood cultures under the most carefully controlled conditions. In a dozen or more typical cases of atrophic arthritis he got positive blood cultures in about 50 per cent but streptococci in only one. The others contained diphtheroids. The latter may be of some interest in view of claims that they can be transmuted into streptococci. Nature would be playing a mean trick indeed if an organism that appears so frequently in blood cultures, that apparently produces immune reactions in the patient's serum, and that produces such a typical experimental arthritis in animals, would turn out to be nothing but a harmless contamination.

DR. RUSSELL L. HADEN, Cleveland: Dr. Wainwright's paper emphasizes one significant trend: Regardless of the isolation of this or that germ, or treatment by this or that method, the chief problem is to study the patient and see what happens to him. Dr. Wainwright talks of patients' hypersensitivity. In considering the problem of chronic arthritis, it would appear that certain "normal persons" are not, and perhaps never will become, sensitive or liable thereto whereas another individual will. In addition to isolating organisms and removing foci,

one must study the other underlying characteristics of the patient. The correction of his altered soil may be more important than removing a focus, which is but the beginning of treatment.

DR. JOSEPH L. MILLER, Chicago: Physicians of this country have been slow to recognize the essential differences between atrophic and hypertrophic arthritis. It seems almost certain that they are two distinct diseases, hypertrophic arthritis being merely a degenerative disease. The rapidity with which certain patients get well after removal of an infected tooth makes me think that there is at times a profound psychologic effect therefrom. I saw one patient with arthritis recently who four weeks before had had a bad tooth removed. Before she got home from the dentist she was "all well." Recently she read of somebody dying of arthritis, and now her pain is back. Regardless of such instances, however, I approve of the removal of foci and the use of vaccines in addition to other measures of recognized merit.

DR. ARTHUR STEINDLER, Iowa City: Many patients, as I have mentioned, were unable to have a complete focal check for various reasons. At least 800 did have a complete search for foci, and of this group a small but definite percentage gave a satisfactory response to removal of foci. By response I don't mean cure; I mean that they obtained subjective relief, which was maintained for a considerable length of time.

DR. CHARLES W. WAINWRIGHT, Baltimore: May I say to Dr. Key that I feel that the vaccine has more than a psychic effect. Not uncommonly patients had a degree or two of fever with the initial injection, but when this occurred the subsequent dose was lessened, or at least not increased, and no further febrile responses generally were noted. Occasionally a particularly sensitive patient would experience a febrile reaction after the first three or four injections. In such cases much small doses were used until the reactive phase disappeared.

Nutritional Factors in Chronic Arthritis

DRS. FRANK J. SLADEN, DWIGHT C. ENSIGN and CLARKE M. McCOLL, Detroit: Since 1928 we have been studying the eating habits of patients with chronic arthritis and of persons without arthritis. The dietary habits of a patient in the hospital even on a full diet cannot be considered as being his normal one, as his choice of food is not strictly within his control but lies within that of the dietitian and the markets from which she buys. We sought therefore to get a record of what such patients were eating at home under established habits. Records were kept on units of a week; thus, the normal daily fluctuations were minimized. One hundred and thirty-eight patients with chronic arthritis were studied; of these, 128 had hypertrophic arthritis and only ten had atrophic (rheumatoid) arthritis. In the study of a series of 148 persons without arthritis the average daily intake was 1,840 calories, protein 60 Gm., fat 84 Gm. and carbohydrate 211 Gm. These values are contrasted with the average intake of patients with arthritis: 1,609 calories, protein 52 Gm., fat 73 Gm. and carbohydrate 185 Gm. These figures do not suggest that people with chronic arthritis are accustomed to dietary indulgence in any respect, certainly not in carbohydrates, as we understand it is not unusual for active, normal people to consume as high as 450 Gm. of carbohydrate daily.

In spite of this, however, a craving for sweets was commonly confessed, and on closer analysis of the carbohydrate intake we found an otherwise hidden dietary error, a tendency to choose for their carbohydrate foods that may be called nonprotective foodstuffs, with resultant inadequacy in their intake of carbohydrates on the list of protective foods. Thus they favored sugars and sweets, refined cereals and pastries, potatoes and white flour and were shy on the use of unrefined cereals, dairy products, and fruits and vegetables, carbohydrates that contain large amounts of bulk and of the protective substances, minerals and vitamins. These observations were made the basis of therapeutic correction. The patients were encouraged to change the emphasis on the choice of carbohydrates used, to alter their type and not their amount. We have noted definite improvement in weight curves, bowel function, condition of the joints, and the general efficiency and well being of patients with both types of chronic arthritis.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to *THE JOURNAL* in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Yeast or Vitamin B₂ in Treatment of Pernicious Anemia.—The Lassens treated eight patients having typical pernicious anemia with various yeast preparations, given partly without additions of any kind, partly after incubation with normal gastric juice. These yeast preparations were assayed by tests on rats as to their contents of vitamins B₁ and B₂. One preparation that contained no B₁ was found to be highly

effective against experimental vitamin B₂ deficiency in rats. The extrinsic factor searched for by Castle is not identical with vitamin B₂ or B₁, and presumably not with any other fraction of the vitamin B complex. Yeast appears to be either completely without any antianemic effect or it possibly contains minimal amounts of antianemic factor. On addition of normal gastric juice it has not been practicable with any degree of certainty to ascertain an increase in the content of active antianemic principle.

Vaccination Against Acute Anterior Poliomyelitis.—Kolmer hesitates to advise the subcutaneous injection of a poliomyelitis vaccine known to contain some living virus, even though he believes it to be devitalized sufficiently with sodium ricinoleate to make it safe. He believes that three subcutaneous injections of this kind of vaccine at intervals of from five to seven days and in a dose of from 0.05 to 0.1 cc. per kilogram of weight is an effective method for vaccination against acute anterior poliomyelitis. If it is true that human beings acquire immunity to acute anterior poliomyelitis by contact with the virus even without demonstrable evidences of infection, it would appear that less vaccine may be required relatively to body weight than in the case of monkeys, especially since less antibody is probably required for the protection of human beings against small amounts of virus entering the upper respiratory tract than is required for the protection of monkeys inoculated intracerebrally with from fifteen to twenty minimal infective doses. Since these vaccines never produced the slightest evidence of infection, the author is vaccinating a group of children varying in age from 8 months to 15 years. The first dose has been 0.25 cc. for children less than 3 years of age and 0.5 cc. for older children up to 15 years. Varying amounts are being given in the second and third doses. Since the cord of a large monkey will yield about 200 cc. of vaccine, this will make sufficient vaccine for the immunization of fifty or more children.

Encephalitis in Children Apparently Congenital and Following Maternal Influenza.—Stewart reports seven cases that appear to present congenital encephalitis. The patients were born of mothers suffering with influenza in the later months of pregnancy. None of these women had symptoms suggestive of epidemic encephalitis. All survived the disease as far as can be determined, and none show any signs of the sequelae of encephalitis. The children, on the other hand, show character defects typical of postencephalitic behavior change, and in five cases there is evidence of organic involvement of the extrapyramidal system. Their symptoms have existed apparently from the time of birth. They give no history of acute illness, nor in any case did the onset of the symptoms coincide with the occurrence of one of the usual diseases of childhood. In five there is sufficient evidence of organic involvement of the extrapyramidal system to verify the diagnosis of encephalitic sequelae. Four are parkinsonian in type, while the fifth presents choreiform tremors, which are increasing in severity. The sixth case gives a definite history of lethargy, which was noticed at birth. Examination of the pupils revealed the reverse Argyll Robertson phenomenon. The seventh was the only patient in whom the physical observations were negative. Here the diagnosis was based on the type of behavior disorder. The majority of the cases, therefore, present both the behavior disorder as well as the organic signs characteristic of the sequelae of epidemic encephalitis. They appear to be congenital and follow maternal influenza. The hypothesis that the influenza bacillus may be the etiologic factor in epidemic encephalitis is suggested by the work of Crofton, as well as that of the author in collaboration with Evans.

Influence of Glycine on Creatinuria in Peripheral Neuritis.—Allinson and his associates observed a case of toxic peripheral neuritis with atrophy and creatinuria. Daily analyses were made of the urinary excretion of creatinine, creatine, nitrogen and sulphur. In contrast with other cases of secondary muscular atrophy, but like those with progressive muscular dystrophy and myasthenia gravis, the ingestion of glycine increased the creatinuria markedly. As the patient's condition improved, the creatinuria decreased and the reaction of glycine diminished correspondingly.

Gas Bacillus Infection Complicating Laparotomy.—Nason and Starr say that this condition is manifested by a fulminating clinical course, which may rapidly terminate fatally. Despite the widespread prevalence of the anaerobic bacilli, gas bacillus infection following laparotomy is relatively rare. The organisms have been identified in the discharge from abdominal drainage tracts. The gas bacillus has been isolated from the biliary tract and liver immediately after death. The infection may begin in the muscle of the abdominal wall, the peritoneal cavity or the liver. The pathologic changes are the result of the toxemia alone or of the toxemia plus the presence of organisms and gas. When muscle is involved it becomes edematous, necrotic and crepitant. The clinical picture is one of overwhelming toxemia. Within six to twelve hours after operation, certain alarming signs may appear in a patient whose postoperative recovery has been proceeding satisfactorily. If the infection involves the abdominal wall, crepitation may be elicited early. Of late the literature has contained many reports describing the clinical aspects of postoperative "liver deaths." Heyd, in discussing this entity, described three distinct types, one of which was similar to the clinical picture existing in gas bacillus toxemia and septicemia. The similarity in the clinical manifestations of gas bacillus toxemia and those of hepatorenal insufficiency indicates that actually acute insufficiency exists as a result of gas bacillus toxemia. It is conceivable that in some cases the element of hepatorenal insufficiency may be primary, with the gas bacillus infection engrafted on an already necrotizing, degenerating liver. Measures directed at lowering the temperature, combating the toxemia and supporting the circulation are indicated. Specific antitoxin should be given. Intravenous and subcutaneous infusions of large quantities of sodium chloride and dextrose solutions may be used in an attempt to offset the shock and toxemia. Concentrated solutions of dextrose are indicated because of the extensive damage to the liver and because of the need for a diuretic. At the first suggestion of this complication, large doses of gas bacillus antitoxin should be administered intravenously. The usual skin test for sensitivity should be performed. From one to four therapeutic doses of polyvalent antitoxin containing at least 10,000 units each of *Bacillus welchii* and *Vibrio septique* antitoxin per dose should serve as the initial administration. An additional therapeutic dose should be given intramuscularly. The intravenous administration of antitoxin should be repeated every two to four hours during the crucial period. If crepitation is elicited in the wound, the sutures should be removed, the wound laid open and smears of the exudate taken. Free incisions may be necessary if the process is extensive. Hydrogen dioxide or surgical solution of chlorinated soda may be instilled into the wound at frequent intervals. When the infection involves the blood

stream, peritoneum or liver, the outlook seems hopeless. The prognosis in cases of the infection localized in the abdominal wall depends on the virulence of the particular bacterial strain, the severity of the toxemia and the resistance of the patient. Death occurred in the authors' four cases.

Primary Liposarcoma of Bone.—Barnard reports a case which, from the clinical and pathologic study, suggests strongly a periosteal origin of a liposarcoma which involved the upper part of the arm. The fact that fatty tumors termed "lipoma" may undergo sarcomatous change gave at first the impression that this was such a tumor. There were, however, several factors that did not coincide with this point of view. Of the tumors that have been reported, few involved the upper extremity and did not involve the bone but arose in the fascial planes from a preexisting lipoma, which was always encapsulated, and the history of its presence preceded for long periods its malignant change. The clinical picture in the present case was more characteristic of so-called periosteal sarcomas, but the pathologic observations did not fit this classification. That this was not a benign periosteal lipoma which had undergone sarcomatous change would seem evident from the lack of encapsulation and the absence of a tumor prior to the onset of severe symptoms. The osseous involvement was apparent in the earliest roentgenogram, and at the time of biopsy there was no infiltration of the subdeltoid sheath, which would have been a more logical site for local metastases or invasion than the cortical bone if the tumor had arisen extraperiosteally. The histologic picture of the tumor both locally and in the myriad of small metastases in the lungs, which were not demonstrable roentgenologically, suggests that this was a tumor of fatty origin. There was evidence of trauma from repeated dislocations of the shoulder, which was assumed to have been a factor in the origin or spread of this new growth.

Operation for Double Harelip.—Lee stresses the necessity for early operation in double harelip but states that it is not justifiable until the baby's weight curve is definitely rising and the weight is at least as much as at the time of birth. Ether administered by a motor driven insufflation apparatus is satisfactory, after the patient has been anesthetized lightly with the ether cone. The first step to ensure symmetry is obtained by placing a single stitch of silk as a marker in the midline of the premaxilla at its free edge after a small bit of vermilion border has been removed from that region. Two other stitches as markers are placed through the upper lip at each nostril but inferior to the point where the lip is to be cut across. Both sides of the upper lip should be undercut near the alveolar process, care being taken to remain close to the bone. An incision is then made in each lateral part of the upper lip, as much as possible of the lip that is already formed being used. The incision should afford relaxation in order to bring the respective segments to the midline of the face, therefore it may be necessary to extend the incision almost parallel with the

vermillion border. It is desirable to have a slight redundancy, as the excess tissue contracts and gives a better result. The small amount of crimson border that is superior is then removed with a scalpel, care being taken not to enter far into the nostril. After the remaining thin vermillion border on the premaxilla has been removed, care should be taken to leave as much normal skin as possible, and the lateral parts of the new upper lip are brought together in the midline to see whether enough relaxation is present, since thorough and complete relaxation of these lateral pedicles is essential to the repair. The first row of sutures is of silk and is placed with a number three French needle. These sutures are placed first at the nostril of one side, and they approximate the posterior and deeper aspects of the opposing surfaces. The knots are placed on the mucous surface and the threads are cut short. The interrupted suturing is carried anteriorly to the free margin of the newly formed lip and the sutures are placed into the lip and into some of the fibrocartilage in the premaxilla if necessary. The second row of sutures consists of three interrupted sutures of 000 plain catgut: the first suture is put well into the remaining upper lip and into the premaxilla, a similar stitch is placed on the opposite side and a third stitch is placed at the apex of the premaxilla at its junction with the two flaps. The third row of sutures can be either of horsehair or of silk and consists of bringing together the skin anteriorly. In order to ensure neat approximation and a small scar, it is advantageous to use a suture like an end-on-mattress stitch. A 1 inch piece of a number eight French, soft rubber catheter is inserted into each nostril and held in place with a suture to ensure patency. Compound tincture of benzoin boiled down to a soft putty-like consistency is applied to the sutures in the skin. A Logan bow is attached by means of adhesive strips to the cheeks immediately after operation. This may be left on for two weeks and the muscles of the face should be kept at rest. To this end as much as 3 grains (0.2 Gm.) of sodium bromide every two hours may be necessary. Keeping the patient quiet after operation is more important than the use of the Logan bow. The baby should be fed at the regular intervals normal for its age by means of a medicine dropper to which the terminal portion of a soft rubber catheter has been attached. Sutures can be removed at any time after the sixth day. Minor corrective operations may have to be performed to adjust the vermillion border or to excise portions of a broad scar. These operative measures should be done within three months of the original operation. Massage of the scar and nursing should not be allowed until five weeks after operation. The author gives the results in three cases of double harelip.

Effect of High Fat Meal on Respiratory Quotient.—

Bowen and his associates discuss the possibility that a qualitative metabolic variation exists in the obese person. This variation from the normal is based on the observation of a lower *postabsorptive respiratory quotient* in the obese subject. They observed the effect of a large fat meal on twelve normal subjects, six of whom were slightly underweight, twenty nondiabetic obese and eleven obese diabetic subjects. The absorptive respiratory quotients indicate that the food mixture during this absorption is approximately the same in normal and obese persons. This response in the diabetic obese group suggests that less carbohydrate was being consumed during the utilization of fat. The observations were extended long enough to demonstrate the returning trend of the respiratory quotient to the *postabsorptive level*. No correlation between the curves of the absorptive respiratory quotient and the curves of the specific dynamic action could be demonstrated. A specific dynamic action of fat was present in all groups. It was found to be approximately the same in the obese and the normal persons. This action, however, was considerably greater in the obese diabetic patients.

Mesenteric Vascular Occlusion.—Dunphy and Zollinger observed five cases of mesenteric vascular occlusion. The first four terminated fatally. In only two was a diagnosis of mesenteric thrombosis even considered and in only one of these was operation performed. Although the clinical picture varied considerably, several important features were recognized in

each case. 1. It was observed that regardless of the duration of the attack the clinical picture was not typical of any of the common surgical emergencies. It was not the problem of a mistaken diagnosis but of no diagnosis. However, the patients were ill obviously from an abdominal lesion that simulated obstruction. 2. The character of the pain in each case was out of proportion to the clinical picture. A significant characteristic of the pain was its persistence after the usual measures for its relief had been instituted. 3. The only constant physical observation was abdominal tenderness, more or less generalized, with rebound tenderness referred to the point of pressure. 4. All the patients had a high leukocytosis and a high or mounting pulse rate with a temperature that was normal or only slightly elevated. It was evident in each case that there was a gastrointestinal disturbance, but this was not manifested in any constant manner. Difficulty in moving the bowels without complete obstruction was seen in all cases. Vomiting was variable. Rapidly progressing shock was seen in one case. As a direct result of this study the fifth case of mesenteric vascular occlusion was recognized as such and an early and successful resection was performed. The authors do not maintain that the features outlined are essential to diagnosis, for the white count may be as misleading in this disease as in others. However, they feel that these features when present render a diagnosis much more tenable than previous observations would indicate.

The Postoperative Enema.—Countryman emphasizes the fact that the routine use of enemas postoperatively often ordered by the house physician or supervising nurse is rather a sad procedure in the light of present day knowledge of the colon. He believes that one of the most important things in assisting the postoperative patient to regain normal intestinal activity is to give the intestine some lubricant and soft bulky material to work on. For the last two years his postoperative routine has been to give, from twenty-four to thirty-six hours after operation, or as soon as the patient's stomach will tolerate it, 1 ounce (30 cc.) of liquid petrolatum with agar morning and evening. The rectal tube is used liberally from the beginning and the Levine tube is used when indicated in upper abdominal distention. The patient is encouraged to drink hot water, tea and black coffee. Cold tap water is allowed as desired unless there is considerable nausea and vomiting. A 5 per cent sodium bicarbonate and dextrose proctoclysis is used, one hour on and two hours off, until the stomach tolerates fluids. Pantopon, one-third grain (0.02 Gm.), is given as often as necessary to keep the patient comfortable. The cases in which the author has used this procedure have included gastro-enterostomy, cholecystectomy, acute intestinal obstruction, one with intestinal resection, hysterectomy and operations, such as salpingitis, both chronic and subacute, gangrenous and perforative appendicitis and the usual major abdominal surgery, both chronic and acute.

- *Fracture of Hip Joint (Intracapsular): New Method of Skeletal Fixation. A. T. Moore, Columbia.—p. 199.
Indications for Surgery of Thyroid Gland. L. H. McCalla, Greenville.—p. 205.

Skeletal Fixation for Fracture of Hip Joint.—Moore describes a method of skeletal fixation for intracapsular fractures of the neck of the femur. After local preparation, from 20 to 40 cc. of a 2 per cent solution of procaine hydrochloride is injected directly into the hip joint. The needle is inserted at a point about two thirds the distance from the anterior superior spine to the top of the great trochanter. The direction is approximately toward the coccyx and enough solution is injected to fill the joint completely. The needle is withdrawn and a few cubic centimeters of the anesthetic is infiltrated into the skin and subcutaneous tissue below the greater trochanter, where a small incision is to be made. After a few minutes the hip is absolutely anesthetized. There is complete muscular relaxation, and reduction of the fracture can be accomplished by any method that the operator prefers. An incision of from 2 to 3 inches is made just below the great trochanter, exposing the lateral surface of the upper end of the femur. Three drill-pointed stainless steel pins, three thirty-seconds of an inch thick, are passed through the neck up into the head. The pins are inserted at varying angles, which fasten the head securely in position. The angle and length of the femoral neck may be determined by the Westcott technic. The average length of the drills is about 3½ inches. Protruding ends of the drills must be left so that subsequent removal is easy. These ends may vary from one-fourth to three-fourths inch or more. There is no danger of drilling through the head and acetabulum because one always stops short of the full length of the pin. After roentgenograms are taken, the pin is easily pushed in for the desired distance. The position of the reduction and of the pins is checked by roentgenogram or the fluoroscope. When the pins are in perfect position, six drill holes are made through the neck and up into the head, in addition to the holes in which the pins remain inserted, ensuring a better blood supply. A piece of wood is placed on the outer side of the femur and given a light blow with the mallet, ensuring that the fragments are driven well together. The wound is closed with two or three interrupted sutures. The patient can immediately move the hip freely in all directions, and this is encouraged so as to give the patient confidence in the strength of the fixation. The patient is put back to bed and told to turn, twist or do anything that he pleases so long as he stays in bed. The operation is almost free from shock. There has been nothing to cause shock if a gentle reduction has been done. The next day the patient may be up with assistance or using crutches. In a few days he may be dismissed from the hospital. The patient should use crutches for about six months.

Certain Practical Considerations Concerning the Hemolytic System in Complement Fixation Tests, with Note on Standardization of Droppers for Wassermann Test. E. J. Wyler.—p. 521.

Serologic Study of Streptolysins.—Todd states that hemolytic streptococci from human infections produce an antigenic streptolysin which is serologically group specific but not type specific. In addition to this antigenic form of streptolysin, which is subject to reversible oxidation and reduction, they also produce another variety of streptolysin which is not subject to reversible oxidation and reduction and which appears to have no antigenic activity. The streptolysins of hemolytic streptococci from animal infections do not appear to be antigens and they are not subject to reversible oxidation and reduction. Soluble streptolysin prepared from "pseudo-hemolytic" streptococci appears to be nonantigenic. Lancefield's groups of hemolytic streptococci each produce different varieties of streptolysin which may be distinguished from each other by their reactions to oxygen, to heat and to acid. Serums with a high titer of antistreptolysin from hyperimmunized horses neutralize tetanolysin and pneumococcal hemolysin to a limited extent. The degree of neutralization is not necessarily correlated with the antistreptolysin titer, and the different hemolysins are distinguishable by quantitative serologic methods. This partial antigenic overlapping of hemolysins can be demonstrated only by the use of hyperimmune serums; it is not seen when the comparatively low titrated antistreptolysin serums of

patients infected with hemolytic streptococci are examined and it therefore does not interfere with the use of antistreptolysin titers for the diagnosis of streptococcal infections. The hemolysin of staphylococci is not serologically related to streptolysin.

Preparation of Nutrient Agar.—Wright points out that as in broth, so also in agar, the early addition of peptone results in more stable and satisfactory mediums for certain organisms. The diameter of colonies of streptococci, pneumococci, corynebacteria and some other organisms is not affected by the omission of dextrose but is considerably affected if peptone is not present in adequate amounts. Thick layers of agar and a low concentration of agar favor the production of large colonies of pneumococci, streptococci and corynebacteria. The addition of blood or serum to agar results in the formation of large colonies; the amount required is about the same for the two. The size of the colony appears to be influenced more by the amount of the available foodstuff than by the accumulation of by-products of growth. Filtration through thick filtering layers may cause marked deterioration of broth; it has less effect on agar, but mediums filtered through glass wool or thin paper tend to yield larger colonies.

Cultivation of Plague Bacillus.—Wright observed that the growth of small inoculums of plague bacilli is sometimes suppressed by oxidized constituents of broth prepared with the late addition of peptone. The plague bacillus is destroyed moderately rapidly if exposed to more than about 1 per cent of oxygen at 37 C. For aerobic surface cultivation of small inoculums blood (0.1 per cent), serum (10 per cent) or sodium sulphite (0.05 per cent or less) needs to be added to the agar. Such mediums yield maximal growth aerobically at 37 C. Aerobic growth occurs in broth without such additions. The plague bacillus dies within twenty-four hours in solutions of sodium chloride even under anaerobic conditions, especially if exposed at a temperature of 37 C.

Agglutinin Response to Recent Antienterica Vaccination.—Stuart and Krikorian's experiments reveal that in human beings O agglutinin formation takes place as readily and often in as high degree after inoculation with suitable antienterica vaccines as it does during the course of enteric disease. In this respect a better response has been obtained with non-phenolized vaccines than with those preserved even for a short time in low concentrations of phenol. An explanation has been sought in the apparently adverse, although admittedly unknown, effect exercised by the phenol on the heat-stable antigen. It

is known that when typhoid immune serum is brought into contact with the phenol-preserved suspension of *Bacillus typhosus* known as Ficker's diagnosticum, the O agglutination fails altogether. It is suggested that in ordinary T and TAB vaccines the exposure of the O agglutininogen to the action of phenol over varying periods of time may lead ultimately to a loss of antigenic power and thus to an absence of O agglutinins in the vaccinated persons' serums. Arkwright concludes that "the heat-stable, smooth O agglutininogen is probably identical with the antigen which produces resistance and with the smooth heat-stable agglutinable substance." It is agreed that in order to be efficient an antityphoid vaccine should produce antibodies against the stable antigen; but all antienterica vaccines do effect to a greater or lesser extent the formation of O agglutinins in the majority of human beings, provided such vaccines are of relatively recent manufacture and administered in adequately interspaced dosage. It is not, therefore, a question of finding a method of vaccination that will fulfil this demand for O agglutinin production but a method that will ensure the maximal production and persistence of these antibodies. The authors believe that antienterica vaccines issued without the addition of a preservative, and inoculated shortly after preparation, best meet the case. The appearance and persistence of O agglutinins in significant titers follow in human beings and in rabbits the use of ordinary recently prepared antienterica vaccines but would appear to be more marked in the case of vaccines to which no phenol has been added as a preservative.

Cooley's Anemia.—Moncrieff and Whitby believe that Cooley's anemia appears to be a definite clinical entity and is probably a blood dyscrasia appearing as a recessive in the Mediterranean races and that it is comparable to the sickle cell anemia of the negroid peoples. They describe a case in a child, aged 1½ years, of Greek parents, which will provide an opportunity for further observation in that the mother is again pregnant and the infant after birth can be examined to determine whether it also has inherited the condition and, if so, at what age it is first evident. The patient itself did not respond to treatment with iron, and a blood transfusion produced some definite improvement. At an attempt at a second transfusion the patient died under the anesthetic. The authors emphasize that, though Cooley has clearly defined a disease entity, the features do not express the concept of von Jaksch's anemia as understood by English pediatricians. Advances in hematology and clinical knowledge prevent the inclusion of leukemic cases in the von Jaksch category, and the syndrome is no longer a convenient dumping ground for all the unexplained anemias and splenomegalies of infancy. Von Jaksch's anemia is a useful term even though the conception of it must be somewhat elastic. The term implies that in the opinion of the clinician and hematologist the prognosis is not hopeless—a feature emphasized by von Jaksch. In contrast to Cooley's group, there is not only this relatively favorable outlook if treatment with iron or transfusion is energetically pursued but there are also no constant familial trait and no bony changes other than those due to associated rickets—a by no means invariable complication. Von Jaksch's anemia appears to be a subacute hemolytic anemia, probably the result of infection in which there is in addition to the red cell changes a definite reaction on the part of the leukoblastic tissue resulting in the appearance of myeloid cells in the blood.

Acute Postoperative Dilatation of Stomach Complicated by Perforation. J. Rousset.—p. 1518.

Endocrine Roentgen Stimulation.—Lehmann believes that the roentgen rays may stimulate the endocrine glands and that when this occurs it is a functional phenomenon entirely different from the phenomenon of cellular destruction. He used irradiations corresponding to 200 kilovolts filtered through 0.8 mm. of copper and 2 mm. of aluminum. The apparatus includes a Casel generator and a Coolidge Mégat tube. Only the trunk and head were irradiated at separate sessions. A dose of 20 roentgens was used at each session for the trunk and 30 roentgens for the head. The intervals between sessions varied from ten to fourteen days, depending on the duration of treatment. As a result of observations on animals, he believes that the roentgen produced priapism is identical with that produced by the injection of the urine of pregnancy. Clinically he has treated eleven patients affected with ovarian insufficiency. In two there were no results. In the nine others there was improvement after from three to six sessions. In eight other cases, postpuberty ovarian insufficiency existed. In six of these there was an increased abundance of the menstrual flow. He therefore concludes that roentgen therapy constitutes an excellent procedure for functional stimulation and that it offers a new means of action in endocrine therapy.

Vaccination Against Whooping Cough.—According to Rosenbusch, vaccine therapy of whooping cough is still in dispute, but he thinks that the authors who observed mostly failures worked with ineffective vaccines. He administered concentrated vaccines in sixty-seven cases. In forty-six the vaccine was promptly effective, in ten the results were somewhat retarded, in three the results were doubtful, and in eight the vaccinothrapy was a failure. Many of the children who promptly responded to the vaccinothrapy were not of a suggestible age, and this, together with the fact that none of the other therapeutic measures produced such favorable results, seems to indicate the possibility of a specific action. However, it is difficult to furnish definite proof of the specificity, but the factors that are cited to disprove specificity likewise fail to convince. On the basis of his experiences, the author recommends the use of the vaccine. Failures are encountered in all forms of treatment, and only extensive use will solve the problem.

Thyroid Tissue Under Influence of Growth Stimuli.—Silberberg investigated how several simultaneously acting growth stimuli influence an organ. The thyroid of young, growing guinea-pigs served as the object of experimentation, and it was determined what influence is exerted by potassium, iodide, extract of the anterior lobe of the hypophysis and compensatory hypertrophy following ectomy of a lobe of the thyroid. In the case of simultaneous action of potassium iodide and extract of the anterior lobe of the hypophysis, histologic examination revealed the specific changes that are characteristic of these two stimuli. The extract promotes liquefaction of the colloid, while the potassium iodide counteracts rapid absorption of the softened and liquefied material. This explains the presence of greatly dilated acini and even torn acini. Thus both substances exerted their specific action, while in other portions an intermediate effect was observed in that the acini absorbed considerable amounts of fluid so that their lumens become dilated and their epitheliums somewhat flattened. The

dilatation of the acini was greater than if either extract or potassium iodide were administered alone. However, there was as a rule no summation of the actions and, under certain conditions, the potassium iodide may even reduce the reaction to the extract. If the hypophyseal extract acts as a qualitative growth stimulus on the quantitative proliferation energy of the compensatory hypertrophy of the thyroid, there is an increase in the number of cells as the result of the compensatory hypertrophy and the hypophyseal extract causes qualitative proliferation processes. For the collaboration of these two stimuli that differ in kind and in degree, the sequence of their action and the condition of the thyroid are important. The influence of the hypophyseal extract on the growth of transplanted thyroid tissue was studied on autotransplants and on homeotransplants. In a completely healed-in transplant from a thyroid that had not been treated previously, the hypophyseal extract produced the same typical changes that were produced in the normal thyroid. In homeotransplants there developed a conflict between the destructive action of the homeotoxic elements and the constructive, growth increasing action of the extract.

*Manifestations and Surgical Complications of Ascariasis. F. Virgilio.—p. 734.

*Histologic and Experimental Research on So-Called Enteric Chromaffin Glands. F. Zanardi.—p. 749.

Surgical Complications of Ascariasis.—Virgilio refers to several cases of ascariasis with prevalently surgical manifestations. They are spastic stenosis of the duodenum with ascarids in the duodenum and the stomach, intermittent intestinal occlusion with ascarids in the small intestine, ascariasis simulating appendicitis, ascariasis of the appendix and of the liver, ascariasis with acute diverticulitis of Meckel and ascariasis complicating intestinal perforation due to trauma. The first three cases were diagnosed on roentgen examination, the remaining four on surgical exploration. The author emphasizes the importance of roentgen examination in confirming obscure and deceptive abdominal syndromes due to the presence of the ascarids. In practical surgery, ascariasis is generally diagnosed roentgenologically. In ascariasis, when the intestinal loop is full of opaque liquid, the body of the ascarid shows a streaked shadow, with well defined contours, tapered at the ends, and with a winding course. When the loop contains little barium, it adheres to the body of the parasite, which is then presented as a thin and regular streak delineated by two long parallel opaque lines, sometimes interrupted. When the loop is empty, the worm has the appearance of a long hair. The symptomatology of ascariasis of the gallbladder is the same as that of biliary lithiasis. Therefore diagnosis can only be suspected, especially in children with involvement of the general condition due probably to parasitic toxins. It is always a more delicate and doubtful diagnosis because ascariasis is present in 60 per cent of cases presenting lithiasis of the biliary tract. In cases in which lithiasis is not found it is important to examine closely the pancreas, duodenum and stomach in addition to the gallbladder and the bile tracts in such a way as not to leave unobserved the parasitic lesion that originally caused it. From the surgical point of view, in countries in which ascariasis is prevalent, administration of santonin before operative intervention is a good prophylactic measure. Such remedies as santonin and oil of chenopodium may prevent serious complications in intestinal ascariasis, especially during infancy. In hepatic and biliary ascariasis, only surgical treatment is indicated. Santonin, inducing the death of the parasites, does not aid in their expulsion, and therefore the mechanical disturbance persists. In ascariasis of the gallbladder, cholecystostomy has the advantage of draining the biliary tract, thereby eliminating the parasites found outside the gallbladder. Cholecystectomy prevents the development of numerous parasites from eggs laid in the gallbladder walls,

frequently altered by secondary chronic infection. When the ascarids penetrate into the pancreas, the best treatment is incision into the pancreas and drainage of the pancreas and of the region of the hepatoduodenal fossa. When ascarids are present in the mastoid, the lacrimal canal and the bronchi, surgical intervention is the method of choice.

Research on Enteric Chromaffin Glands.—Zanardi states that the chromo-argentaffine cells of the intestine are present throughout the enteric tube of man and of laboratory animals (dogs and guinea-pigs). They are more numerous in the large intestine and in the appendix of man, while in animals they are more numerous in the small intestine and the first part of the duodenum. They constitute a cellular species in themselves, differentiated from other epithelial elements of the intestinal mucosa by the presence of chromaffin and reductory granules, by the character of the nucleus and by the form and situation of the cell. They are present in the intestinal mucosa of the human fetus at the third month; at first they are more in evidence in the upper segments of the small intestine, but after the fifth month they appear in the large intestine and the appendix. Normally they do not exist in the human stomach or at least are scarce in that location. But they have appeared in cases of simple gastritis or gastritis associated with ulcer or carcinoma, in correspondence to the areas of intestinal metaplasia. No information has been obtained favoring the connective tissue origin of these cells either from the experimental study of regenerative processes or from the study of ulcerations, inflammations and tumors of the gastro-intestinal mucosa. The cells do not seem to take an active part in the regenerative processes of the gastro-intestinal mucosa, in that they are missing in the defect which recovers in a short time the loss of substance and that they appear only when the epithelium is perfectly differentiated; there they participate indirectly in the process of regeneration and are constantly more numerous in the zones bordering on the defect. The large chromo-argentaffine cells present in the mucosa of the chorion and in the submucosa of the large intestine of the guinea-pig (and sometimes of the human appendix) are clearly differentiated from the chromo-argentaffine cells of the epithelium by morphologic characteristics and thus may be classified as histiocytes. The author concludes that these cells may be explained as ganglionic cells, newly formed by multiplication of the preexisting ones and distinguishable from them by their argentaffine granule characteristics.

Allergic Cutaneous Symptoms in Venereal Ulcer. F. Brunetti and G. Serra.—p. 513.

Deviation of Complement in Gonorrhea.—Boncinelli studied the deviation of the complement reaction with gonococcus antigen on 243 patients, the total number of serum reactions amounting to 280. One group comprised definite gonorrheal patients. A second group comprised subjects free from gonorrhea, a third, patients presenting clinically gonococcic disease forms, and a fourth, syphilitic patients showing positive or negative Wassermann reactions and being free from or affected by gonorrhea. In the first group the reaction was positive in 77 per cent of the cases; the simple gonococcus forms gave 56 per cent of positive reactions, while the more complicated forms were 89.7 per cent positive. In the group of subjects free from gonorrhea, the reaction was positive in only four cases (5 per cent), while the group in which gonorrhea was clinically evident showed 76 per cent of positive reactions. In the last group, consisting of syphilitic patients free from or affected by gonorrhea, the reactions were negative whenever gonorrhea was absent. In cases in which syphilis was accompanied by gonorrhea, the reaction was negative when the Wassermann reaction was positive and vice versa. The author concludes that the deviation of the complement reaction is sensitive and specific and that it merits wider application in diagnostic practice.

 Pustulate Exophthalmos: Surgical Therapy; Case. A. J. Manes.—p. 773.

Gastric Cancer.—Goyena and d'Amato report twenty-eight cases of gastric cancer and conclude that atypical forms are frequent (36 per cent). The febrile acute form gave a frequency of 7 per cent. The fever in this form is, as a rule, of a continuous and irregular type and may not be high. The febrile acute form may be interpreted, from the anatomopathologic point of view, as an association of gastric ulcerous tumors and a permanent infection. Whether the infection is the cause or the consequence of the ulcers cannot be asserted. The most frequent atypical form of gastric cancer is the juvenile form (14 per cent). On account of its high frequency this form may be suspected even in patients less than 30 years of age. In the authors' group of the juvenile form, the two sexes were affected in the same proportion (7 per cent each in women and in men). This observation is not in agreement with the opinion of Mienter, who states that this form is more frequent in men than in women. Juvenile cancer develops at an earlier age in women than in man and its evolution is more rapid and grave in female than in male patients. If anachlorhydria is of diagnostic importance in gastric cancer, hyperchlorhydria or even the mere presence of free hydrochloric acid in the gastric secretions is not a negative sign for the diagnosis of gastric cancer. Marked hyperchlorhydria may be present in cases of pure gastric cancer without previous symptoms of peptic ulcer. The mental condition of patients suffering from the psychopathic form is probably due both to anemia, caused by a tumoral vasoconstriction and resulting in a diminished cerebral blood supply, and to the impregnation of the nervous cells by gastric toxins of tumoral origin. The form of gastric cancer with conservation of the appetite may develop in patients at any age, and not necessarily in patients with the juvenile form as Le Noir and Riege say. The appetite of patients with gastric cancer may change under various influences of mechanical or psychic nature and these influences may appear in the course of the disease and cause a transformation of the anorectic type into a type having normal appetite or even bulimia.

 Scleroderma and Mucous Membrane. J. Sella.—p. 464.

Isolated Chancre-Like Facial Pyoderma.—Hoffmann observed a number of patients who had isolated chancre-like pyodermias on the face. In some patients the lesion appeared on the eyelid, in others on the temple or on the lip. While the genital form of the isolated pyoderma is most frequent in children, the facial type seems to predominate in adults. The chancre-like pyoderma appears nearly always as an isolated focus and presents a syphilitic or a vacciniiform aspect in that it resembles a button-like, eroded, ulcerated primary lesion. The characteristics are the firm basis of the lesion, the superficial and rather smooth ulceration, the scrous discharge, the red color of the narrow eroded rim, the yellowish or dark crust and the firm swelling of the lymph nodes. It appears that the process has an especial affinity for delicate tissue. The author considers justified the assumption that maceration with urine plays a part in the genital lesions, and he points out that the localization of the facial pyodermias indicates that tears and saliva may play a similar part. The process usually begins

with a blister and heals within four to six weeks. The differentiation from syphilitic and other specific lesions is important not only in the isolated chancre-like pyodermias that appear on the genitalia and on the oral mucous membrane but also in those that appear on the face. The absence of spirochetes, of Paschen's bodies and of Guarneri's bodies in repeated tests and the rapid disappearance of the process and of the swelling of the lymph nodes following the application of anti-impetiginous remedies are important factors in the differential diagnosis. The fact that after several months an isolated relapse may appear on a symmetrical site is worthy of note.

Functional Disturbances of Liver in Skin Diseases.—In functional tests of the liver, Döllken found that the gelatin-water tolerance test of Mancke and Rohr gave satisfactory results. He made tests on 180 persons to determine the behavior of the liver in persons who had the same disorder. A tabular report lists the various disorders in which the functional test of the liver was made, the number of patients and the outcome of the test. A disturbance of the liver was detected in about 15 per cent of the cases. The test revealed that patients with psoriasis were free from hepatic impairment. In the patients with eczema, the results of the test were too dubious to give the possibility of a more strict classification, for in more than 10 per cent the test indicated a disturbance of the liver, while in the others the test was negative. Conditions were similar in syphilis. However, liver impairment was demonstrable in all cases of dermatitis exfoliativa and in arspenamine dermatitis. In arspenamine dermatitis the behavior of the liver was especially noteworthy, because the functional disturbance of the liver was no longer demonstrable after the disappearance of the cutaneous lesion.

Test for Determination of Hepatic Function.—The bile acid tolerance test described by Nakagawa and his associates is conducted in the following manner: On the empty stomach the patients are given 200 Gm. of bread with butter and 100 cc. of milk. This comparatively dry diet is given in order to avoid an excessive quantity of urine, which would make the test ambiguous. Within thirty minutes after this breakfast the patient completely voids the urine that serves as the control specimen. Then 1.5 cc. of a 20 per cent solution of a bile acid is slowly injected into the cubital vein. After this injection, the patient has to void every thirty minutes until the second hour. Of each of these specimens 1 cc. is put into Widal tubes, and one drop of acetic acid is added. In addition to this, Hay's test is done on the filtered urine, and the urobilinogen and the urobilin are determined by means of Ehrlich's and Schlesinger's reagents. The test is considered positive if the specimens of urine eliminated after the injection show (1) a white turbidity following the addition of acetic acid, (2) a positive Hay's test and (3) urobilinogen and urobilin in larger quantities than in the control specimen. The authors performed this test on normal persons and on patients with hepatic disorders. In cholelithiasis, chronic cholecystitis and cirrhosis of the liver the test was positive, and, since the discharge of the bile was not obstructed, it may be concluded that the positive outcome of the test is due to the reduced capacity of the diseased liver to intercept and eliminate the injected bile acid. However, the bile acid tolerance test does not indicate whether the other functions of the liver are impaired. But since this intercepting and eliminating function seems to be the one that is impaired the earliest and in the largest number of cases, the test will generally reveal whether there is an impairment of the hepatic functions or not. The test is of course without value for the differential diagnosis.

Atropine in Angina Pectoris.—According to Scherf and Schnabel, atropine increases the frequency of the heart. On the basis of observations they stress that in angina pectoris great precaution is necessary in the use of remedies that increase the cardiac frequency. They show that in arteriosclerotic and syphilitic coronary stenosis atropine, because of its accelerating influence on the heart action, may lead to dangerous disturbances in the blood perfusion of the cardiac muscle.

Auto-Urotherapy.—Krebs shows that it is possible to influence favorably allergic and spastic conditions with the intramuscular injection of a child's own urine. He observed prompt improvement in children with hay fever and with asthma. He usually injected 0.5 cc. of the urine. The injections were repeated at intervals of from two to twelve days. The favorable results obtained in hay fever and asthma induced the author to try the treatment in spastic conditions of an entirely different type; namely, in those that were probably caused by obstetric injuries. Here too improvement was noted, but the author admits that this improvement is not a complete cure. Nevertheless, he thinks that auto-urotherapy deserves a trial in pediatrics, particularly in children with hay fever or asthma. The effective substance of urotherapy is still unknown; its efficacy is due neither to nonspecific protein bodies nor to antigen action.

Pathology and Treatment of Thrombosis.—In studies on the predisposition to thrombosis, Neuda found that in the majority of patients with thrombosis auto-agglutinating substances are present, which agglutinate at room temperature not only their own erythrocytes but also erythrocytes of other persons of the same group and of group O. Tests prove that the substances are true auto-antibodies. Further experiments revealed that the addition of liver extract prevented the auto-antibody reaction, and this led to the introduction of liver therapy. The author employed it in thirty-five cases. With the exception of one patient, who died, all others recovered in a comparatively short time following intramuscular injections of liver extract. The liver treatment should begin as early as possible. In cases in which the sugar content of the blood is increased, the carbohydrate intake should be reduced. The fact that the agglutinating substances are active particularly at lower temperatures indicates the value of heat in the treatment of thrombosis. The injections of liver extract are continued until the pain subsides and the swelling is going down. This is usually the case after from three to six injections.

Strophanthin in Treatment of Angina Pectoris.—Edens shows that angina pectoris has lost much of its terror since the introduction of strophanthin therapy. Strophanthin is especially valuable in angina pectoris that develops in older persons with coronary sclerosis but is ineffective in angina pectoris produced by vasomotor factors. Thus strophanthin therapy may aid in the differentiation of angina pectoris of organic origin from that due to vasomotor factors. The author stresses that as a rule only the intravenous administration of digitalis preparations, particularly strophanthin, brings the desired results, while the oral and even the intramuscular administrations fail.

***New Observations in Simmond's Disease.** K. Herman.—p. 1460.

Coalescence of Labia Minora During Childhood. H. Schlack.—p. 1465.

Toxin of Menstruation.—Mommsen shows that it cannot be doubted that there is a menstrual toxin. However, he thinks that terms such as menotoxin should be avoided, because they are misleading. The menstrual toxin may be demonstrated by the arresting influence on the growth of germinating lupines and by the arrest of the yeast fermentation of dextrose. The toxin appears in considerable quantities in the milk of a lactating menstruating woman. Even if there is no genital bleeding, the toxin is eliminated at intervals of three or four weeks soon after delivery. The author considers an unfavorable effect of the menstrual toxin on persons in the environment as practically nonexistent, because even the nursing never develops serious disturbances. The slight disorders, such as diarrhea and paleness, that occasionally develop in the nursing are physiologic. The nature of the toxin is not known, but the author assumes that it is a substance originating in the lipid metabolism and belonging to the group of biogenic amines.

Simmond's Disease.—Herman describes three cases of Simmond's disease (hypophyseal cachexia). Its most important symptoms are severe cachexia and emaciation. Cachexia may be the only symptom. The author lists as the most characteristic symptoms white, pale skin, an old facial expression, rapid aging, falling out of teeth and hair, cessation of menstruation, impotence, reduced blood pressure and blood sugar, apathy, insomnia, lack of appetite, pressure and pain in the gastric region after eating, vomiting, and occasionally anacidity and constipation. The body temperature is lowered, there is a feeling of cold, particularly in the feet, also pruritus and occasionally pathologic changes in the region of the sella (calcified foci, xanthomatous infiltrations). The specific dynamic action is often lacking and the basal metabolism is reduced. Examination of the blood discloses anemia and occasionally there is eosinophilia. The author obtained favorable therapeutic results with hormones of the anterior lobe of the hypophysis. He found that these hormones had a greater effect on the metabolism than on the function of the genital glands. He emphasizes that the treatment with hormones of the anterior lobe of the hypophysis may eventually have diagnostic value, for if a cachexia quickly responds to treatment with these hormones the disorder is Simmond's disease.

Treatment of Enteritis Caused by Lambliæ.—In the stool of a patient with an enterocolitis, which had been refractory to dietary and medicinal treatment, Lada discovered Lambliæ. By means of the duodenal tube he introduced into the duodenum of the patient a solution of 0.3 Gm. of neoarsphenamine in 200 cc. of water. The diarrhea ceased at once, and two days later the stools were of normal color and consistency. On the third day the stools were entirely free from the organisms but in spite of after-treatment with acetarsone they reappeared later. However, there was no relapse of the clinical symptoms. To destroy the organisms the administration of neoarsphenamine by means of the duodenal tube was repeated several times and was followed by renewed treatment with acetarsone. As the result of these measures they disappeared completely within ten days, and the author states that ten weeks after the treatment the patient was free from symptoms, the stools were always normal and repeated search for Lambliæ always gave negative results. He points out that the literature reports other cases in which arsenic preparations produced such

favorable results but that there are also cases in which this therapy fails completely. However, he thinks that it should always be tried. To avoid relapses, the patients should be warned that dietary mistakes and colds are likely to cause a relapse.

Sedimentation Speed in Tuberculosis.—Balancescu and Oeriu review the theories of the mechanism of sedimentation of erythrocytes. They describe the technic of their modification of the Westergren method. They found that in healthy persons the Westergren method and the Balancescu-Oeriu method disclose identical values of sedimentation speed. In patients with phthisis, the Balancescu-Oeriu method is less sensitive than the Westergren method. The authors consider the lesser sensitivity of the Balancescu-Oeriu method as an advantage in that the sedimentation values are less influenced by various factors. In cases of severe pulmonary tuberculosis it is sufficient to read the reaction after thirty minutes and after one hour, but in less severe cases a reading should be taken again after two hours and in rare cases also after twenty-four hours. The authors found that the sedimentation speed runs parallel with the course of the disease; the longer the duration of the tuberculous process and the greater the sedimentation speed the more unfavorable is the prognosis, but it is not permissible to base the prognosis exclusively on the sedimentation speed. The determination of the sedimentation speed is simple and gives quick results. Together with the clinical, biochemical and bacteriologic data it is of value in the diagnosis and prognosis of tuberculosis.

Blood Chlorides in Hyperemesis of Pregnancy.—Kretzschmar points out that hyperemesis may lead to hypochloremia and then discusses the development of hypochloremia and the cause of the increase in rest nitrogen in hypochloremia. He describes the symptoms that are common to the various disorders in which there exist hypochloremia and increase in the rest nitrogen. There is nearly always a considerable loss of fluid and of sodium chloride, which leads to dehydration and later to toxicosis. The skin as well as the other tissues is slack and withered. There is general prostration. The abdomen is drawn in so that in pregnant women the uterus may stand out. The blood pressure is reduced and the pulse is weak but rapid. The temperature increases and edemas may appear, while the renal function is insufficient. Icterus develops, the vomiting becomes continuous and diarrhea may develop in hyperemesis of pregnancy. The cause of the first nausea and vomiting is not definitely known as yet, but there are indications that changes in the central nervous system are responsible. The continuation of the vomiting, however, is frequently due to psychic factors, and during this stage it can often be arrested by suggestion. However, if manifestations of dehydration have set in, the psychotherapy must be combined with measures that refill the depleted water and sodium chloride depots. The author points out that sodium chloride is an old folk remedy in the treatment of vomiting and states that enemas of physiologic solution of sodium chloride and the intravenous injection of sodium chloride have been found helpful in cases of hyperemesis. He thinks that the interruption of pregnancy is justified only if the hyperemesis and severe toxic symptoms persist in spite of the administration of fluid and of sodium chloride.

Hidradenoma of Vulva.—Eichenberg describes twelve cases of hidradenoma of the vulva. The nodules were in the subcutaneous tissue and varied in size from that of a pea to that of an almond. In ten cases the growth was on the large labium and in two cases on the small labium. The author describes the histology of the growths, and he states that they are not always benign. He states that the hidradenoma of the vulva is a congenital malformation of the sweat glands. The

dilated sweat glands in the surroundings, the concurrence of a cystic hyperplasia of the sweat glands with a hidradenoma and anomalies of the regional striated muscles indicate developmental disturbances. The most common form of the hidradenoma is the intracystic papilloma. Large pale epitheliomas, which are a characteristic of mammary tumors, are also found in hidradenoma. A carcinoma may develop on the basis of a hidradenoma, but this is a comparatively rare occurrence. Indefinite demarcation, multistratification of the epithelium, strands of pavement epithelium and horny pearls occur quite frequently and as such do not justify the diagnosis of carcinoma; however, the transition to carcinoma is gradual and purely quantitative, and only experience gained by the comparison of clinical with anatomopathologic aspects will make the dividing line clear. The author thinks that in all cases the nodules should be extirpated and histologically examined and the patients reexamined.

*Congenital Dystrophia Brevicollis: Case. T. E. H. Thaysen.—p. 998.

Renal Rickets.—Svendsgaard describes three cases of chronic nephritis, dwarfism and rachitic changes in the bones, in a boy aged 15, a boy aged 3 and a girl aged 20 months, respectively. In the last two cases, uremia caused death; necropsy disclosed renal atrophy and atrophy of the thymus, together with rachitic changes in the bones. She asserts that the actual theories as to the cause of renal rickets fail to explain all cases.

Congenital Dystrophia Brevicollis.—Thaysen's patient, a woman aged 24, has the typical deformity of the neck without synostosis of the cervical vertebrae that is seen in Klippel-Feil's disease. He says that the abnormal shape of the cranium and the asymmetry of the face indicate defective development of the cranium during fetal life. The anomaly has caused a hypoplasia of the hypophysis by a contracting sella turcica, and this abnormality is regarded as the cause of the patient's dwarfism, genital atrophy, osteoporosis and delayed closing of the epiphyses. Her retarded mental development is believed to be due to the abnormal cranial development.

PRACTICAL MEASURES IN THE PREVENTION AND TREATMENT OF PUERPERAL SEPSIS

B. P. WATSON, M.D. (EDIN.), F.R.C.S. (EDIN.)
NEW YORK

The cause, prevention and treatment of puerperal sepsis have been discussed since obstetrics began to have a literature of its own. It is held as a reproach to the medical profession that puerperal sepsis still continues to take such a large toll of human life and that efforts for its prevention and cure have fallen far short of success. Of late years there has been much criticism in the lay press regarding the present state of affairs. Such publicity is good so far as it stimulates improvement, but, since much that is written distorts the facts or puts them in the wrong perspective, it is harmful. That the medical profession is alive to the problem is evidenced by the vast amount of work being done on it in every part of the world, and by the voluminous literature that has accumulated in the past ten years.

Space will not permit of even a partial review of that literature, so for the purposes of this communication it will be referred to only as it has a bearing on present conceptions of etiology and on practical measures of prevention and treatment.

PREVENTION

Puerperal sepsis is the disease *par excellence* to which the dictum "prevention is better than cure" is applicable; for when once a virulent organism has gained access to the puerperal uterus with its large venous sinuses, its abundant, dilated lymphatic channels and its constant muscular activity, the chances of a massive invasion of the blood and lymph streams are very great, and the patient may quickly be overwhelmed in spite of any means of treatment that are available at the present time.

Relative to the prevention of puerperal sepsis, a distinction must be made between the exogenous method of infection by organisms from without and the endogenous method of infection by organisms already present in the body of the patient. In exogenous infection the most common invading organism is one of the streptococcus group, and the most virulent of these is the hemolytic streptococcus.

How do such organisms gain access to the uterus? Obviously, they may be conveyed directly to the genital tract by the fingers of the attendant if he has a streptococcal lesion on his hands when he makes a vaginal examination. One must not lose sight of the possibility

of the patient herself introducing her fingers into the vagina during the course of labor, or of coitus occurring shortly before. Such occurrences are probably much more frequent than is generally assumed. There must be few instances today of a physician with an obvious infective lesion on his hand taking an active part in the conduct of a labor. The wrongfulness of such a proceeding is so obvious that nothing more need be said about it.

There are, however, more subtle ways in which the streptococcus may gain access to the uterus. It is a widely distributed organism and it can reach the human organism through various channels, causing in one case tonsillitis, in another mastoiditis, pneumonia or scarlet fever. It is impossible to determine the manner in which the individual inoculation takes place, and so it may be with uterine infection. There is general agreement that the same streptococcus which is responsible for all these diseases is responsible also for puerperal sepsis, and there is accumulated evidence showing that streptococcal puerperal infections are most frequent when these other diseases are prevalent in the community.

The hemolytic streptococcus does not survive long outside the body, so that it is seldom possible to recover it even from the immediate environs of an infected patient. It is, however, very frequently found in the nose and throat of individuals in attendance on such patients and of many persons who have had no known direct contact. The proportion of apparently healthy individuals who harbor the hemolytic streptococcus in the nose or the throat is put as high as 45 per cent by Davis,¹ and the occurrence in individuals with tonsillar crypts is placed at 100 per cent by Pilot and Davis.² Hare³ has recently shown that virulent streptococci are obtained from the throats and the noses of individuals with infection of the respiratory tract, even though there are few symptoms. His test of virulence is the power of the organisms to resist phagocytosis in normal human blood.

There are now many recorded instances in which by agglutinin absorption tests the organism in the throat and the nose of the attendant and that recovered from a case of puerperal sepsis have been proved to be identical.

One of the most striking instances of this kind was recorded recently by Smith.⁴ A physician attended three patients in their own homes, situated three miles apart. Streptococcal septicemia developed in all three and all of them died. In regard to this instance, Smith writes:

Serological examination showed that all strains obtained from the uteri and blood of the three patients were identical with that obtained from the doctor's throat. Not only so, but during

her brief illness at home Mrs. J. S., was attended by her sister, Mrs. G., and this woman developed a severe tonsillitis on the day following the removal of Mrs. J. S. The tonsillitis was followed by an acute otitis, and from the pus a hemolytic streptococcus serologically identical with the other strains was also cultured.

Smith records other almost equally striking cases, and the literature of the past few years recounts many more. One is therefore driven to the conclusion that the nose and throat carrier of *Streptococcus haemolyticus* is the cause of the great majority both of the sporadic form and of the epidemic form of hemolytic streptococcal puerperal infections.

In order to emphasize the practical measures that can be taken to prevent or minimize the danger of hemolytic streptococcal infections, I shall outline briefly the routine carried out in my service in the Sloane Hospital for Women.

1. *Detection of Carriers.*—Cultures from the throat and nose are taken in a routine manner from all persons, including the physicians, students and nurses who may come in contact with women in labor or in the puerperium. All pupil nurses must bring with them from their respective schools a certificate of a negative hemolytic streptococcus culture from the nose and throat. Individuals from whom positive cultures are obtained are excluded from the direct care of patients, and the throat and nose are treated with 2 per cent solution of neosilvol. Duty is resumed when two successive cultures are negative.

2. *Use of Masks.*—Thorough masking of the nose and mouth is obligatory on every one who comes in contact with a woman at any stage of labor or during the puerperium. The mask is of four thicknesses of gauze and must completely cover the nose as well as the mouth. It must be worn by every one in the labor and delivery rooms, and by every nurse doing a perineal dressing in the wards. I believe that many patients are infected in the early puerperium and I lay great stress on the masking of the nurses in the wards. This insistence on masking savors of fussiness and is apt to be "pooh-poohed" and resented at first. However, it very quickly becomes a routine and is taken as much for granted as is the masking of the nurses, operator, assistants and spectators in the surgical operating room.

One of the hazards of hospital obstetrics is the number of contacts for each patient during labor and during the puerperium. For the past year we have kept a record of the contacts of each individual patient; by contacts is meant individuals who actually come in physical contact with the patient. In the case of ward patients the number of contacts during the course of labor has been as high as twenty-five; the average number is eleven. It should be stated that ours is a teaching institution.

With such potentialities for infection, the minimum precaution requires the effective masking of all such contacts.

3. *Isolation of Infected Cases.*—In the prevention of exogenous infection the isolation of frankly infected cases is obviously of great importance. Isolation should also be extended as will be detailed later, to all patients who may be carriers of the streptococcus in the genital tract, even though such patients are free of symptoms. The personnel in contact with these patients should not contact well patients, as such individuals are very likely to be carriers.

It may seem to some that undue emphasis has been placed on the carrier as the responsible agent in puer-

peral infection of exogenous origin, but from my personal experience and from a study of the literature of recent years I am convinced that the carrier is the major menace. Recognized carriers should, therefore, be excluded from attendance on obstetric patients, and as any one at any time may unwittingly be a carrier, proper masking should be used to protect the attendants' hands, gloves, dressings, instruments and external genitalia of the patients from that fine spraying from the mouth and nose which always occurs when one speaks or even breathes.

VAGINAL EXAMINATION

With this protection of the sterile field surrounding the patient, I do not believe that properly executed vaginal examinations are a menace to the patient. Penner and Gegerson, two members of this year's graduating class of the Columbia University College of Physicians and Surgeons, made a study of the morbidity of the patients in Sloane Hospital who had and who had not had a vaginal examination in the course of labor. They used for the study only strictly comparable cases. These studies indicated that there was no increased morbidity in those examined vaginally. I have never approved of rectal examinations during labor and this study encourages me to continue the use of vaginal examinations in the cases in which the procedure is necessary.

The vaginal examination must be made only with full exposure of the vulva and perineum, with thorough sponging off of the area surrounding the vaginal orifice, complete separation of the labia, and the absolutely direct introduction of the examining fingers without outside contamination. In this way, providing the gloves are sterile and the examiner is properly masked, the danger of introducing pathogenic organisms is reduced to a minimum. At the same time, the risk of introducing into the cervix and lower uterine segment organisms already present in the vagina is less than when the vaginal wall itself is pushed up into the cervix, as must occur during a rectal examination.

PLACE OF DELIVERY

A statistical investigation by Robinson, a member of the graduating class of the Columbia University College of Physicians and Surgeons, shows that the proportion of deaths from puerperal sepsis in relation to the total deaths is highest in the states in which the largest number of births takes place in hospitals, and that it is lowest in the states in which there is a larger percentage of home deliveries. Deaths from accidents of labor are lowest in the states with the highest percentage of hospitalization and highest in the states with the highest percentage of home deliveries. This would seem to prove that the hospital would be the safest place for the obstetric patient if sepsis could be controlled. There is, undoubtedly, a greater risk of contagion and of infection by carriers in the hospital, especially if the hospital is not properly planned, has no provision for isolation of infected cases and has an uncontrolled staff.

During the present year, we have made, for the first time, systematic cultures from the vagina of every patient in labor. During the months of January, February, March and April sixteen patients out of a total of 500 on whom cultures were made showed a hemolytic streptococcus in the vagina. None of these patients were febrile at the time, but all were isolated. Nine continued to harbor the streptococcus in the vagina during the puerperium but fever developed in

only one, and that was very mild. Three of the other seven patients had a mildly morbid puerperium, although the streptococcus could not be recovered after delivery.

During the spring months of this year streptococcal infections of all kinds have been prevalent in New York, but we have not had a single case of serious streptococcal infection in the Sloane Hospital. It may be mere coincidence, but it may be possible that our isolation of these nonfebrile streptococcus carriers has prevented other serious infections. The results of the work being done emphasize the need of constant watchfulness in every hospital in which obstetric patients are treated. Without proper control and without a proper structural arrangement an obstetric hospital may well be a less safe place for a patient than even the meanest home. It seems to me that the time is ripe for a revaluation of scope of home delivery for the normal case, and I would commend attention to the exhibit arranged by Dr. Plass in the Scientific Exhibit.

PREVENTION OF ENDOGENOUS INFECTION

The vagina of every pregnant woman and of every woman in labor contains organisms. These vaginal organisms ascend into the cervix and lower uterine segment in the later stages of labor and continue to do so in the early puerperium, so that by the third day the normal puerperal uterine cavity is heavily invaded, and it does not become sterile until the tenth or twelfth day.

Most of these organisms are not pathogens, but in a certain percentage of women there are present in the vagina during labor, and in the uterus in the early puerperium, organisms which by ordinary cultural tests are identical with those obtained from definite inflammatory lesions; yet, these women may show no febrile reaction. The potential pathogens most commonly found are various types of the nonhemolytic aerobic streptococcus: the anaerobic streptococcus, the staphylococcus and *Bacillus coli*. The hemolytic streptococcus is found in only from 1 to 3 per cent of individuals.

As I have previously mentioned, this organism was found in 3 per cent of the cases in the Sloane Hospital. The fact that no serious infection developed in any of our patients is in accord with reports from other clinics. Is this so because the individual patient has developed an immunity to her own organisms or is it because of the fact that the organisms are really nonvirulent?

According to Hare,⁵ these vaginal streptococci found in nonfebrile cases are nonvirulent, as evidenced by their feeble resistance to phagocytosis in normal blood. It is known that the pathogenicity of the anaerobic streptococci as tested in laboratory animals is very small and in many instances altogether absent, and yet they may cause a very extensive and sometimes fatal puerperal sepsis. As more and more work is being done on these anaerobes, it would seem that they are responsible for the majority of the cases of mild and moderate puerperal infection, for many of the cases of thrombophlebitis and for not a few true septicemias.

There must be circumstances, therefore, under which all these apparently nonvirulent pathogens may become virulent and cause infection. The problem of the prevention of these infections must, therefore, be approached in two ways: (1) the elimination of the organisms from the genital tract before or during labor and (2) the avoidance of conditions that favor their acquisition of virulence.

Vaginal Antiseptics.—Douching of the vagina with antiseptic solutions during labor was suggested and

practiced many years ago. The method was discarded when it was shown that the agents employed destroyed the vaginal bacillus of Döderlein, which by maintaining an acid environment inhibited the growth of other organisms. In the last ten years there have been renewed attempts to render the parturient canal sterile. Mayes⁵ has been the chief proponent. He uses a solution of mercurochrome, which is instilled into the vagina at regular intervals during labor. He states that the septic death rate has practically been halved since the method was used. I have always felt that there were other factors responsible for the results which he undoubtedly obtained, especially the more careful supervision of all technic in the cases in which mercurochrome was used. This opinion is supported by the fact that it has been shown by Garrod⁶ and others that mercurochrome is a very feeble germicide, in no way comparable with, for instance, brilliant green or iodine.

Colebrook⁷ criticizes the indirect evidence of lowered morbidity and mortality rates. He has carried out experiments on five women, using mercurochrome and other antiseptics, checking bacterial content of the vagina, before, during and after the treatment.

In regard to the results of these experiments he says:

These five records show that the genital tract was not sterilized in any instance, following the repeated application of mercurochrome, crystal violet and brilliant green, or dettol. In two cases there were approximately as many organisms grown three hours after the first treatment as before. In all probability this failure is attributable to multiplication of the bacteria somewhere, perhaps, in the glands of the cervical canal, out of reach of the antiseptic.

The outstanding feature of the results is that in four of the five cases the bacterial species originally present, species believed to be of little or no pathogenicity, were replaced or joined by other species of definitely greater pathogenicity; e. g., *B. coli*, *B. proteus*, hemolytic staphylococcus and fecal streptococcus. It would seem probable that the introduction of the chemical agent had so altered the mucosal cells or their secretions as to permit these species, which are not normally present, to establish themselves.

Although the number of cases is admittedly small this investigation suggests the tentative conclusion that it is inadvisable to attempt to improve upon nature's arrangements for keeping the genital tract free from pathogenic bacteria.

Holding the view expressed by Colebrook, I have never systematically used vaginal antiseptics, but I have an open mind on the subject and am more than willing to adopt any method when it is proved to be efficacious.

Control of Conditions Favoring Endogenous Infection.—In studying the cases of febrile morbidity in the Sloane Hospital for Women we find that the three most commonly associated conditions are prolonged labor, extensive lacerations and excessive hemorrhage. These are all conditions which in their inception and in their control favor exogenous infection; but with a uniform technic for all cases it is fair to assume that the consistently higher incidence of infection under the circumstances mentioned is due, at least in part, to the activation of organisms already present in the vagina.

The avoidance of these three prime factors can be accomplished only by the exercise of the best obstetric judgment and technical skill. An increased morbidity does not follow a high incidence of low forceps deliveries if these are done with skill and gentleness, but it does follow a high incidence of mid forceps and

5. Mayes, H. W.: *Am. J. Obst. & Gynec.* 10: 1 (July) 1925; *ibid.* 23: 627 (May) 1932; *Surg., Gynec. & Obst.* 54: 529 (Oct.) 1932.

6. Garrod, L. P.: *Brit. M. J.* 1: 572 (April 4) 1931.

7. Colebrook, L., and Maxted, W. R.: *J. Obst. & Gynaec. Brit. Emp.* 40: 966 (Oct.) 1933.

high forceps deliveries, and it does follow a high incidence of prolonged labors, whether these ultimately terminate normally or are completed by operation.

Given a definite indication for operative delivery and given the conditions necessary for its proper performance, the sooner it is done the better. The proved parallelism between increased operative intervention and increased septic morbidity and mortality is due to that intervention being performed, in many instances, on wrong indications, at the wrong time and by unskilled operators. General improvement will result only when it is recognized by every practitioner that a large number of obstetric procedures are of major surgical importance, that they can be undertaken with impunity only by one who has had special training, and that even in skilled hands the results will be disastrous if the procedure is attempted at the wrong time or in the wrong case.

TREATMENT OF PUERPERAL INFECTIONS

I confess that I approach this part of my subject with a sense of futility for, like the late Whitridge Williams, I am more or less of a fatalist so far as the outcome of a case of puerperal infection is concerned. That outcome depends mostly on the virulence and invasiveness of the infecting organism, and to a lesser extent on the tissue reaction and resistance of the individual. So far, no specific has been found that will act with certainty on the organism or its toxins, so one must fall back on the second line of defense and do everything possible to increase the resistance of the tissue. Elsewhere,⁸ I have summarized the present day knowledge regarding antibacterial and antitoxic serums, vaccines and nonspecific therapy. Space will not permit a recapitulation of these, so I shall limit myself to a short summary of the method of treatment we employ in cases of puerperal infection in my service.

When a puerperal patient shows an oral temperature of 100.4 F. or higher on two readings at intervals of four hours, she is transferred to the isolation unit and individualized in all details of nursing care in one of the glass-screened cubicles in a ten-bed ward. A thorough general examination of the throat, lungs, heart and kidneys is made. The uterus is palpated abdominally, the lochia is examined, a culture is taken from the vagina and a blood culture is made. If the uterus is tender and larger than it ought to be, an ice-bag is placed over it and the patient is given three oral doses of 5 grains (0.3 Gm.) of quinine sulphate daily. If the lochia is profuse or foul, the shoulders are elevated in the Gatch frame. The diet is light and nourishing; a small enema is given daily and, if necessary, a mild cathartic, such as magnesia magma, is used. In the majority of cases beginning in this way the condition is an endometritis, which may be due to a variety of organisms with a probable preponderance of the anaerobic streptococcus. Most of these patients make a rapid recovery with no other treatment, so that in a few days the temperature falls to normal, the uterus begins to involute normally, and the lochia becomes less profuse and loses its odor. With this probable outcome we are careful to do nothing that might favor an extension of the infection beyond the uterus. No pelvic examination is made other than to inspect any perineal lacerations and take a culture from just within the vaginal introitus. The uterus is not manipulated from the abdomen.

If the temperature does not fall, one of four things is happening: (1) The infection in the uterus is continuing but remaining localized. (2) Extension has taken place to the pelvic cellular tissue. (3) Infection has extended to the pelvic veins (septic thrombophlebitis). 4. There is invasion of the blood stream. Cultures of the blood are made regularly so long as fever persists. If the patient shows a progressive anemia, or is losing ground, a blood transfusion of 500 cc. is given by the direct method. This may be repeated every three or four days, the amount given each time being from 250 to 400 cc. No vaginal or bimanual examination is made, unless the culture from the vagina has been indeterminate, in which case, with the utmost gentleness, a culture is taken from within the cervix.

If it appears from the negative blood culture and from the absence of the signs of thrombophlebitis, that the infection is still limited to the uterus, we continue to pursue a course of masterly inactivity. We do not use glycerin injections into the uterus nor the introduction of drains with irrigation, as advocated by some, because we believe that in most cases they may do more harm than good. I can still recall the frequency of chills following intra-uterine irrigations during my intern days.

A thrombophlebitis will be indicated by costovertebral tenderness and tenderness over one or both sides of the pelvic brim, a fluctuating temperature, high leukocytic count and sometimes definite chills. Many cases of thrombophlebitis, however, show only a low grade temperature, perhaps not over 100 F., over a period of a week or ten days, and at the end of that time declare themselves by the occurrence of an embolus and a pulmonary infarct. We have observed this so often that we are highly suspicious of all such low grade temperatures unless something definite can be found to account for them. Therefore, we keep such patients in bed until the temperature has been normal for several days.

In cases in which an embolus occurs there is usually marked dyspnea and orthopnea. The patient is propped up and given a hypodermic injection of morphine. In severe cases an oxygen tent may be necessary. Enemas are stopped and she is kept quiet with codeine, from one-half to 1 grain (from 0.03 to 0.065 Gm.), every four hours. Small meals are given every two hours. The patient is kept in bed until the white cell count of the blood is normal and the temperature has been normal for a week.

The majority of these patients with thrombophlebitis, even with an embolus, recover. So far I have not undertaken any of the formidable operative procedures recommended and practiced by obstetricians in this and other countries, such as transperitoneal or extraperitoneal ligation of the pelvic veins, excision of the thrombosed veins and removal of the uterus with drainage through the vagina. In two cases I was very much tempted to operate but forebore, and the patients recovered.

Our operative treatment of puerperal infections at Sloane Hospital is limited. A pelvic abscess is opened, but we are never in a hurry to explore those massive cellulitic exudates which are sometimes found, until there is definite evidence of softening and fluctuation. Most of these exudates absorb without suppuration. We drain the peritoneum through the posterior fornix or through a small incision above the pubes in cases of early peritonitis following septic abortion, and in the rare early case following full term delivery. The peri-

8. Watson, B. P., in Curtis, A. H.: *Obstetrics and Gynecology*, Philadelphia, W. B. Saunders Company 2, 1933.

tonitis developing late in a case of puerperal sepsis is usually just one expression of the wide hematogenous and lymphatic extension, and operation is useless. We never explore or curet the uterus in cases of septic incomplete abortion until the temperature has been normal for three days and we know that the organism is not a hemolytic streptococcus. Cases in which there is excessive hemorrhage, the control of which may necessitate taking the risk of emptying the uterus, constitute the one exception to this rule. I perform a hysterectomy in the rare cases of uterine abscess and of necrosis of a uterine fibroid encountered during the puerperium.

When a definite hematogenous infection is present the case is by no means hopeless. Many patients with a bacteremia recover. It is this fact that makes it so difficult to assess the value of any therapeutic measure employed. We have used various intravenous medications, many types of streptococcus serum, both supposedly antibacterial and antitoxic, and I have not been able to satisfy myself that any one has been of real value in saving a life that would otherwise have been lost.

Hope for the future lies in the work of Warnekros,⁹ Lash and Kaplan¹⁰ and many others who are trying to produce a specific antitoxic serum.

Meantime, blood transfusion has come to be our standby used in the way already mentioned. I have had no experience with immunotransfusion, but those who have used it believe that it may be more efficacious than transfusion from the untreated donor.

620 West One Hundred and Sixty-Eighth Street.

ABSTRACT OF DISCUSSION

DR. J. C. LITZENBERG, Minneapolis: Any contribution leading to the lessening of the mortality of puerperal sepsis is timely. The author has established the thesis that the curative treatment cannot be relied on, it being necessary to direct one's efforts almost exclusively to prevention. The greatest statistical progress in the prevention of puerperal sepsis followed a few years after the work of Semmelweis and Holmes. Since that time, however, the statistics have remained more or less stationary. I wish to emphasize that Dr. Watson has made a distinct contribution by declaring that sepsis due to the hemolytic streptococcus, has been proved by his investigations to be due in a vast majority of cases to a carrier. When rubber gloves were introduced and actually sterile hands became available for the conduct of labor, it was thought that the question of puerperal sepsis would now be solved. Disappointment resulted because of the overconfidence in sterile hands. It was found that the germs were carried in just as frequently by the sterile glove because the genitalia could not be rendered sterile, and that the infection would come from a clean hand carrying germs from outside in. Dr. Watson has emphasized the point that even a sterile hand may carry the infection upward. The carrier, by speaking or even by breathing may bring a fine spray of germs on the genitalia. The author therefore has urged a method of preventing this which he says may appear fussy. However, in the question of puerperal sepsis it is well to be fussy, because results have been entirely unsatisfactory and more or less a reproach on the medical profession. The taking of cultures from carriers in the prevention of all infectious disease has been one of the greatest advances in modern medicine. Dr. Watson has emphasized that there may also be the carrier of the hemolytic streptococcus, which is the most virulent organism and the principal cause of mortality in sepsis. Therefore, I commend his emphasis on this most valuable addition to the prevention of puerperal sepsis, for

prophylaxis is the only solution. The treatment after the infection has occurred is most unsatisfactory.

DR. JOSEPH B. DE LEE, Chicago: Some years ago I collected authentic reports of twenty-nine epidemics of puerperal infections in hospitals, and of the twenty-nine only one hospital had the nerve, the scientific love for verity, to report the epidemic, and that hospital was Dr. Watson's.

DR. A. F. LASH, Chicago: I wish to speak of the statistics in Cook County Hospital in Chicago, which in a sense is comparable in its population to that of New York. In a review of 500 cases of puerperal sepsis last fall it was found that the mortality in home deliveries was four times that of the hospital deliveries; secondly, 35 per cent of the septic patients had operative deliveries, as compared to an incidence of only 6 per cent of operative deliveries in the nonseptic patients. Dr. Watson has well emphasized the importance of bacteriology in reference to infection. I think, as he has demonstrated, that the bacteria may be present and yet the woman will not develop an infection. The explanation is to be found in the patient's healthy local and general immunity, the local immunity consisting of a normal epithelial layer throughout the uterovaginal tract, while the general immunity is made up of the various types of antibodies. I was much surprised not to hear Dr. Watson speak of any experience with the antitoxic streptococcus serum. If there is anything that may improve the patient's general immunity it is the antitoxic serum if it is used early. As in all streptococcal infections, serum is of value only when administered early. If the diagnosis of puerperal sepsis is made early from the typical course of puerperal fever and the presence of a hemolytic streptococcus in the cervix, and if serum is given, the incidence of fatal cases will certainly decrease. I am sure that every one who has had any extensive experience with puerperal sepsis knows that there is a certain group of patients that will develop puerperal sepsis no matter how careful or how skilled the obstetrician is, and it is in such cases that I feel that serum is especially indicated. It has been our experience in the Cook County Hospital that most of our deaths have occurred from puerperal infection following septic abortion in which peritonitis occurs very early in the course.

DR. J. I. HOFBAUER, Cincinnati: Experience in the university clinic of Koenigsberg fully bears out the significance of carriers of streptococci in the conveyance of infection. Masking certainly plays an important part in the prevention of transmission of infection. But the mask must be properly applied. As to the benefit derived from serums in the treatment of puerperal infection, I am rather skeptical. On the other hand, transfusion of between 300 and 400 cc. of blood repeated at proper intervals represents an important element in the treatment. The question why puerperal infections occurring during the early months of pregnancy exhibit a severer course, quite often, than following labor at term may be accounted for by the presence in the parametrium, at term of a well developed defensive mechanism, which is lacking at previous stages of pregnancy.

DR. WILLIAM H. VOGT, St. Louis: So far as the treatment of puerperal sepsis is concerned, I do not believe that physicians are any further today than they were years ago, except perhaps for the use of blood transfusions. Therefore, the prime thing is prevention. In July of last year I took over the service at St. Mary's Hospital in St. Louis and being aware of Dr. Watson's work, namely, the careful masking of the entire personnel and the culturing of noses and throats, I carried this out in detail. It was surprising to see the large number of noses and throats of the nurses, doctors and students that harbored *Streptococcus haemolyticus*. All who showed positive cultures for *Streptococcus haemolyticus* were eliminated from the service and were treated and were not allowed to come back into the department until the condition had entirely cleared up. Furthermore, the entire personnel who go into the nursery have been masked as well, so as to prevent any infections in the respiratory tract of new-born infants. It is, however, interesting to see today what objections are still encountered, and I can readily see what difficulties Semmelweis had in his time when today among the men visiting hospitals some still object to following out the method of masking, gowning and capping themselves for routine examinations. Dr. Watson also

9. Warnekros, K.; Lowros, N., and Becker, N.: München. med. Wehnschr. 73:2155 (Dec. 17) 1926.

10. Lash, A. F., and Kaplan, Bertha: Puerperal Fever; *Streptococcus haemolyticus* Toxin and Antitoxin, J. A. M. A. 86:1197 (April 17) 1926.

brought out another important thing; namely, the masking of the nose as well as the mouth. It is always interesting to me to go into operating rooms and see only the mouth of the operator covered. I dare say that in 75 per cent of operating rooms only the mouth is masked. If it is important to mask the mouth and the nose in obstetrics it would seem to me that it is equally important to do the same thing in surgical work.

DR. B. P. WATSON, New York: There is a good part of my paper which I was unable to read and in which I did enter into some discussion as to the use of serum, especially the antitoxic serum, in the treatment of puerperal sepsis. I think it is only along the line of the work of Warnekros that any strides are likely to be made in the treatment of the disease and in the development of a puerperal antitoxic serum, which, as Dr. Lash says, must be given very early if it is going to do any good at all. The question of whether the patient who harbors hemolytic streptococci in the vagina has a true immunity to that organism, or whether the organism is actually a nonvirulent organism, is still debated. The recent work of Hare would seem to show that most of these organisms in the vagina of nonfebrile patients are really not virulent, but it is not known whether the transfer of that organism to another individual might not make it virulent. I am in entire agreement with Dr. Hofbauer with regard to the defensive mechanism in the periuterine tissue in the later stages of pregnancy, as manifested by the development there of the clasmatoocytes. I am especially grateful to Dr. Vogt for supporting me in the emphasis I have tried to place on the importance of the carrier and the necessity for masking whenever one comes in contact with a woman in labor. Like Dr. Vogt, I also insist on every woman masking in the nursery.

THE MANAGEMENT OF PERFORATED APPENDICITIS

JOHN F. GILE, M.D.

AND

JOHN P. BOWLER, M.D.

HANOVER, N. H.

In hands of average competence and ability, inflammation of the appendix represents a surgical condition that should not and usually does not involve mortality. Yet owing to the lack of appreciation of the significance of early symptoms and because of "home treatment" and delayed surgery, a simple surgical condition progresses to the stage of complications that are ultimately responsible for a tremendous death rate. This is especially appalling when one observes its incidence in the younger age groups. Because of this incidence and the fact that the primary lesion carries no significant danger into later life, appendicitis represents a far more satisfying field for organized educational efforts than do malignant conditions.

We are presenting a review of our cases of appendicitis for the six years from Jan. 1, 1928, to Jan. 1, 1934. Those years have been chosen because with the beginning of that period occurred the opening of Dick Hall's House, the Dartmouth College student infirmary. This is operated as a wing of the Mary Hitchcock Memorial Hospital, which in turn serves a wide rural area. The great majority of the patients of Dick Hall's House are college students who should be expected to have more than average ability to recognize the need of medical attention. They are not surrounded by experts in "home treatment," early medical observation is insured by a system under which janitors report sick students to the medical director, and they are seen from

the beginning by members of our own staff. While it is obvious that this group of cases may be termed preferred risks, it also falls largely within the greatest age incidence of appendicitis, although there are included graduate students and faculty members. We shall consider this as the controlled group. The more miscellaneous patients of the Hitchcock Hospital are referred from distances up to 75 miles and may be considered as the uncontrolled group. And so we discuss two groups of appendicitis cases—controlled and uncontrolled—the only common factor in the management of which is that they have been operated on by the same surgeons.

The controlled group comprises 110 cases with no mortality; the uncontrolled group is one of 791 cases with 17 deaths, a mortality of 2.15 per cent. The total series, therefore, constitutes 901 cases in which operations were performed for appendicitis, with 17 deaths, a mortality of 1.89 per cent.

For the purpose of discussing the cases of perforation, our series has been classified in the following manner:

1. Uncomplicated appendicitis.
2. Acute appendicitis with exudate and local peritonitis.
3. Gangrenous appendicitis with local peritonitis, with or without perforation.
4. Appendiceal abscess.
5. Perforated appendicitis with general peritonitis.

The incidence according to this classification is given in the accompanying table.

It is perfectly apparent that classifications of appendicitis are of little value for comparative purposes, because classification on a basis of conditions found at operation is as variable as the personal interpretation of these conditions by the operating surgeon. It is equally obvious that classification based on the preoperative duration is still more erroneous in assuming that the pathologic process is constant under all conditions and in all individuals. All physicians have seen too many instances in which a six-hour history presents a more serious process in one case than a thirty-six hour duration in another.

Of the total of 901 cases, drainage was done in 235, or 26 per cent, for varying degrees of peritoneal involvement, with sixteen deaths, a mortality of 6.8 per cent. Group 1 is uncomplicated and drainage is not done, and in each series is made up of acute, subacute and chronic cases of operation primarily and solely for appendicitis. All of the ninety patients in the second group were given local drainage with but one fatality, resulting from cerebral embolus in a man, aged 73. While the results of such a conservative attitude toward drainage in the early cases seem satisfactory, one postoperative obstruction occurred in this group, possibly as a result of the presence of drains, but recovery occurred following jejunostomy. In ninety-three cases of gangrenous appendicitis with peritonitis with or without perforation there were six deaths, representing 6.45 per cent. In thirty cases of perforation with local abscess there was one fatality. Of 235 drained cases, we have classified twenty-two as perforated appendicitis with general peritonitis. With such a small number in this group we may have been severe on ourselves, but certainly there is no dilution of the group by false inclusions or by exclusion of any of the six deaths in group 3.

In many previously reported series of appendicitis, divided into two main groups of cases with and with-

out drainage, from 30 to 50 per cent of the total cases in which drainage has been done have been listed as perforation with diffuse peritonitis. According to our criteria we feel that this incidence is high. Under the heading of perforation with general peritonitis we include only those cases with perforation usually of some duration, which beyond any question has resulted in a widespread peritonitis with obvious and extreme toxemia. These cases constitute less than 10 per cent of our cases in which drainage was done. Early perforations with local processes are classified in group 3. But in the latter group we feel that our inability to detect a gross perforation is no guide to the extent or severity of the peritonitis. In other words, bacterial penetration of a gangrenous appendix can produce as profound effects as actual rupture of the wall.

The wide variation in the mortality rate in these groups makes quite clear the effect of the factor of operability or time of operation. There are three stages at which operation is relatively without risk—when the process is limited within the appendix, in the early stages of peritoneal involvement, and after local abscess formation. Early local peritonitis accompanying gangrene with or without perforation carried a mortality rate of 6.45 per cent in a group of ninety-three cases. It could be said that delayed operation in this group might transfer these cases to group 4, appendiceal abscess, in which operation was performed with one half the risk. But there seems no possible assurance that an early process will remain local or that, having become general, it will return to the status of a local process. In delaying surgical intervention in early peritonitis, as in our group 3 with a rate of 6.45 per cent, we have no preoperative basis for prophesying whether the transfer will be to group 4 with abscess formation and a mortality rate of $3\frac{1}{2}$ per cent or to group 5 (that of general peritonitis) with a rate of 36.4 per cent. The only cases in which delay has been a part of the program are those presenting a palpable mass. Twelve of these were delayed from one to three days for preoperative preparation.

We would concede that a program of immediate surgery may have led to operation in cases of already long-established general peritonitis at a time when they represented an almost hopeless risk, which might have been lowered by temporary, supportive medical treatment. But by the same token we would refuse to delay operation in cases of early peritonitis on the basis that it will become a localized abscess. Too many factors of which one can have no preoperative knowledge are concerned. The location of the perforation in one case may be at the tip of a free appendix to be met early by a freely moving omentum; in the next case it may be in the base of an appendix in a field in which bands have fixed surrounding structures in such a position as to allow no mobility for the formation of barriers.

In the last four years we have chosen spinal anesthesia in the great majority of these acute cases. We have used the McBurney incision, which brings one immediately over the site of involvement, permits of no undue exposure or handling of viscera, lends itself to any necessary enlargement, and is best located for the purpose of drainage. As little manipulation of the intestine as possible is carried out and an attempt is always made to remove the appendix in the early cases.

We will take up first those cases in group 3, those with gangrene and local peritonitis, associated in most instances with early perforation. Operation in all cases

in this group was carried out immediately after hospitalization, for reasons not so much concerned with the duration of the process but because the degree of spasm as opposed to distention was by far the predominating sign and because absorption and the resulting toxemia were not presenting a serious risk. Except in the presence of a beginning mass formation, we feel that removal of the appendix in this group and at this time is important and necessary in that it concerns the obliteration of the focal point of the process, which would continue only if the appendix was not removed. In only one in this group of ninety-three cases was the appendix allowed to remain. Although there may be but little fluid in the immediate region of such an appendix, it is often found that there is a considerable collection in the pelvis, and in all these cases drainage has been done with either a tube or a Penrose cigaret in the pelvis. Good care is taken that the omentum lies under this drain, which should not be in contact with or draining through loops of small bowel. A Penrose drain is placed on the stump of the appendix and a third one in the flank. The wound is closed in layers or with through-and-through sutures to the drains. The postoperative care is the same as in the case of general peritonitis and continues as long as necessary on that

program, which will be discussed when we come to this group. We feel that delay in these cases with localized peritonitis, presenting as they do the possibility of progression of the peritoneal involvement, offers us but little opportunity of reducing our mortality in this group.

This series includes thirty cases of appendiceal abscesses. We feel that these represent a process originally and permanently localized, and that they present no problems of peritonitis as such. In any cases in which there has been vomiting with resulting dehydration and a lowering of the general condition, any reasonable preoperative interval is allowable for the restoration of the patient to an acceptable operative condition. In several instances extraperitoneal drainage of the abscess has been possible, either with the primary incision into the mass at some point where it is in contact with the parietal peritoneum or by placing a pack on the unopened peritoneum at the point of closest contact of the mass with the parietes and then waiting for its spontaneous rupture.

When it has been necessary to drain by an incision through the abdominal wall, the appendix has been removed if reasonably accessible and if it could be delivered without the risk of too great dissemination of the infected material. In these cases we feel it imperative that a drain be left in the pelvis even though there may be no signs of involvement of that area at the time of operation, as it has been our experience that the occur-

rence of late pelvic abscesses is too frequent if the pelvis is not drained. The drainage in these cases has been carried out in the same manner as that already described. In this group of thirty cases, seventeen appendixes were removed at the time of the original operation and thirteen were drained without removal. We believe that the manipulation necessary to locate and separate these appendixes with the incidental bleeding and spread of infection is inadvisable and that simple drainage of the abscess is the proper procedure even though it necessitates a second operation. These patients are instructed to return in six months. Several failed to do so and two others returned only after a recurrent abscess had formed.

The twenty-two cases of perforated appendicitis with general peritonitis resulted in eight deaths, or a mortality of 36.4 per cent. Four of these cases represented practically hopeless surgical risks. This entire group is represented by that case which presents abdominal distention as the outstanding sign, less marked abdominal muscular spasm, dehydration, a weak rapid pulse, a pale, drawn expression, and, in some cases, a varying degree of cyanosis. Any preoperative interval in our hands has been short and for the purpose of intensive stimulation. Operation has been carried out in the same manner as in the earlier group. With no attempt at exploration, the appendix has been removed, if possible, which usually is the fact because of the absence of any localizing process. In only three of these cases was the appendix not removed. Drainage is carried out in the same manner as we have described, with the addition of counterdrainage on the left side in the presence of an excessive amount of fluid. The operative procedure is shortened as much as possible, and in this as well as in all cases with any considerable degree of peritoneal involvement no attempt is made at inversion of the appendix stump. These patients are put immediately into Fowler's position. We find it necessary to emphasize in our own institution that the patient be elevated with relation to the floor rather than to the bed. With the introduction of the Gatch type of bed there is no assurance that elevation of the bed means elevation of the patient with regard to the relative positions of the abdomen and the pelvis. These patients are left in Fowler's position for a minimum of forty-eight hours, after which exudative organization has probably occurred. Further maintenance of the position after this time is of little advantage, particularly when balanced against the discomfort of the patient and the difficulty of nursing procedures.

Morphine is continued every four hours in amounts sufficient to produce rest and quiet, the maintenance of a depressed respiratory rate being used as the control. We have found no substitute for morphine. The chewing of gum is started immediately and continued, as this seems the best manner of keeping in condition the mouths of the patients who are to be allowed no oral intake; it is probably of considerable value in preventing secondary parotitis, which may occur in the presence of dehydration. In any case in which a drain is placed in the pelvis and flank no drains are loosened earlier than the sixth postoperative day. It has been our routine procedure to start these patients on subcutaneous saline and dextrose solution intravenously. Subcutaneous administration is useless in cases showing much impairment of the circulation, and here the administration of fluids must be confined to the intravenous route. The period of continuance of intravenous or

subcutaneous fluid administration and absolute restriction by mouth is of course determined by the developments. It is our feeling that warm liquids should be started as early as possible and rapidly followed by food requiring chewing, even though the food is not swallowed.

The problems in connection with these cases are associated, first, with the debility of the patient as a result of the absorption toxemia, and, secondly, with the intestinal obstruction resulting from the peritonitis with paralysis of the bowel or mechanical obstruction developing in the course of the organization of the peritonitis. We purposely avoid the use of the term "paralytic ileus" because of its multiple connotations. We would rather discuss paralytic obstruction accompanying peritonitis on the one hand and mechanical intestinal obstruction on the other, the first to indicate paralysis and the second a true mechanical intestinal obstruction.

The clinical differentiation is obviously difficult, but that patient who from the beginning lies in relative comfort, who insists on the constant presence of an emesis basin under the chin and regurgitates small amounts of fluid at frequent intervals, who maintains a uniform distention, whose abdomen on auscultation gives no sign of peristaltic activity, whose pulse and temperature continue rising and whose opinion of his condition improves as it becomes poorer, has, in our opinion, peritonitis with paralysis of the bowel. In these cases the stomach must be kept empty by an indwelling gastric tube or by intermittent lavage, and the support of intravenous and subcutaneous administration of fluids continued. During the development of this picture one resorts to enemas, intestinal motor stimulants, and stupes.

Mechanical intestinal obstruction as opposed to paralytic obstruction is late in onset, usually appearing between the sixth and tenth postoperative days with an onset marked by nausea and vomiting recurring in a patient who has already reached a point of relative recovery from the original early postoperative condition. The outstanding signs are a steadily rising pulse highly out of proportion to the temperature and with active visible or audible peristaltic activity. A mass may or may not be present. In this group we are confident that enterostomy is life saving, so we do a Witzel enterostomy as rapidly as reasonable. Under local infiltration of the upper left abdominal wall, through a short incision, entrance is made into the first loop of small bowel that presents itself, and the catheter is brought out through a free edge of omentum, which is left to lie directly under the abdominal wound. These patients can stand only the minimal surgical procedure of relief, and secondary exploration with direct attack on the seat of obstruction is too much surgery. One fatality in this group came from just that. No case in which an enterostomy was done required further surgery for the relief of the obstruction.

The differentiation between these two types of obstruction is apt to be more academic than clinically exact when applied to the individual case. If distention and vomiting are not relieved by stomach drainage, dextrose and salines, an enterostomy is to be considered. The general tendency is to postpone this procedure too long. Six of our patients had an enterostomy and a seventh a colostomy for the relief of obstructive symptoms. The colostomy patient survived; three of the six enterostomy patients lived. A fourth patient

lived twelve days following enterostomy, to die finally of a lung complication and to show at autopsy to have had practically no peritonitis remaining. The other three died of extensive peritonitis that was already present at the time of the enterostomy. It is generally recognized that the mechanical obstructive lesions due to local peritonitis are the best adapted for this procedure and that little can be expected from its use in general peritonitis with lack of peristalsis. Pelvic abscess that follows appendicitis with drainage, with its symptoms of rectal tenesmus, diarrhea, pain and fever, can be easily drained through the rectum in the male or the vagina in the female.

We have a certain number of patients each year who after having a stormy convalescence and a suppurating wound have been hastened to recovery by a secondary wound repair. This ordinarily is done between the seventeenth and the twenty-second day after operation and hastens wound healing remarkably. The skin edges are freshened, the muscles drawn together, and a firmer wound with less scar is obtained in a very short time.

CONCLUSION

We have presented a series of 901 cases including a controlled and an uncontrolled group on which is based a discussion of the management of perforated appendicitis of three types: one, gangrenous appendicitis with local peritonitis, associated in the majority of cases with early perforation; two, appendiceal abscess; and, three, perforation with general peritonitis.

This entire series has been managed on a program of operation immediately following an obvious or reasonably founded diagnosis of appendicitis. We are convinced that immediate operation in early peritonitis has aborted the transfer of some of these early cases to the group of diffuse and more long-standing peritonitis, which carries a considerable increase in mortality; that appendiceal abscess represents a lesion originally and throughout its duration restricted to a localized process by the morphology of the right lower abdomen of the individual and presents no emergent needs; and that late general peritonitis involves a mortality that is enormous. But excepting those cases which when first seen obviously present an entirely hopeless surgical risk, there will always remain in this group those cases concerning which it will be difficult to arrive at a decision regarding delay and preoperative treatment.

We have discussed our steps in management which we believe are so orthodox and to which so little addition can be made that improvement in mortality rate so far as we are concerned must come from the possibility of extending in the treatment of appendicitis in general those factors which are concerned in our group of controlled cases: early observation, early diagnosis and early operation. It is almost axiomatic that no item of health instruction in the public school system can offer greater possibilities in the saving of lives than a campaign concerning abdominal pain, laxatives and ice bags in their relation to peritonitis.

The Family Physician.—The family physician must be saved. Upon his salvation depends the future of the medical profession. This can be accomplished by improving his position in the community and providing him with more interesting and more remunerative work.—McFarlane, Andrew: *The Family Physician—Past, Present, Future, New York State J. Med.* 34:579 (July 1) 1934.

THE TREATMENT OF PERITONITIS ASSOCIATED WITH APPENDICITIS

FREDERICK A. COLLIER, M.D.

AND

EUGENE B. POTTER, M.D.

ANN ARBOR, MICH.

In recent years it has become customary to begin articles on acute appendicitis with an apology. Since appendicitis is still the most common acute abdominal lesion, and since its etiology is unknown and its mortality rate is higher than it was fifteen years ago, it would seem that it is still worthy of thoughtful consideration. The mortality of appendicitis in the United States now averages over 20,000 a year. In a majority of these deaths the patients had been in the early decades of life with a good life expectancy.

In 1930, one of us¹ made a study of the patients with acute appendicitis treated in the University Hospital during a period of about four years. It was then our practice to perform an appendectomy as soon as the diagnosis of acute appendicitis was made without regard for the stage of the disease. As a result of that study, we found that the mortality was very low in those patients in whom the infection was limited to the appendix. It was also low in the patients in whom the infection was recent and limited to the right lower quadrant. These patients were largely those in whom the disease had lasted for two days or less. The mortality in patients with spreading peritonitis was shockingly high, and most of the patients of this group were found to have had the disease for from three to five days. An abscess was usually present. In cases in which the preoperative duration of the disease was longer than this, the mortality dropped quite remarkably. Every patient who died had had a purge of some sort, and it was clear that the purge had played an important part in increasing the severity of the disease. These observations confirm those of a large number of other surgeons who have made similar studies.

The vigorous campaign of Bower² and his associates in Philadelphia shows the good that can arise from a campaign directed toward the correction of the evils of late diagnosis, purgation and delayed hospitalization. However, the high mortality that is probably almost universal in this group of patients with general peritonitis has remained as a challenge to surgeons. The mortality in patients with diffusing peritonitis varies widely with different observers from 15 per cent to 65 per cent, with an approximate average of 28 per cent.

A review of the literature on the treatment of peritonitis is confusing and convinces one of the worthlessness of comparing statistics from different clinics in various parts of the world. They can be reconciled only by assuming geographic differences in the degree of severity of the disease. Since the mortality in our patients occurred mainly in patients with diffusing peritonitis and since an improvement in our results could be produced only by a change in the method of handling this group, we determined to treat all patients with acute

From the Department of Surgery, University of Michigan Medical School.

appendicitis whom we suspected of having a spreading peritonitis by the method first advocated by Ochsner³ in 1892.

In this paper we are reporting our experience of the past three years in treating all phases of acute appendicitis, with special reference to the use of deferred operation in patients with spreading peritonitis. We wish to make it perfectly clear that we advocate and practice immediate appendectomy for all patients in whom we believe the disease to be limited to the appendix or its immediate vicinity; we use the deferred operation only in cases of spreading peritonitis. We have

TABLE 1.—General Analysis of Group of Patients Studied

Type	No. of Cases	Deaths	Per Cent Deaths	Average Age	Duration of Disease Before Admission	Average Days in Hospital	Comment
Group 1. Acute appendicitis	213	1	0.46	18.2	22.5 hours	8.4

applied the term "deferred operation" to the treatment advocated by Ochsner so as to emphasize its essentially surgical nature.

A survey of the literature shows that the Ochsner treatment of suppurative peritonitis is used by the minority of surgeons; apparently the number of surgeons advocating the method is decreasing yearly. However, the reported results of its use by Guerry,⁴ Deaver,⁵ Sherren,⁶ Love,⁷ and others are so good that we decided to give it a trial. In 1922, Jopson and Pfeiffer⁸ discussed the method and summarized the literature, which showed a complete lack of accord among American and European surgeons as to their methods of handling patients with spreading peritonitis and with acute appendicitis.

We were disappointed in our search of the literature for detailed information concerning the method, as even the surgeons favoring it have given few details about the clinical course of patients treated by it. It seems to be a method for the treatment of a very serious disease that has proved its ability to give excellent results. We believe that treatment by deferred operation has been gradually losing ground, not through any fault of its own but because its value has not been sufficiently emphasized. The laudable desire of most authors to emphasize immediate operation for acute appendicitis has overshadowed discussion as to the best method of treating acute appendicitis complicated by spreading peritonitis.

This study was made on 336 patients admitted to the University Hospital during the three years from 1931 to 1933, inclusive. All these patients were proved to have had acute appendicitis by operation and examination of

the appendix by the pathologist or, in some instances, by the clinical course of the disease. The patients can be divided roughly into two groups: 1. University students who were referred to us by the University Health Service, an ideal arrangement by which these young and otherwise healthy patients were seen by us early in the course of their disease; the results of treatment in this group were correspondingly good. 2. A group of patients who came to us from long distances relatively late in the course of their disease; among this group were many desperately sick patients.

A general analysis of the entire group of patients is shown in table 1. We have divided the patients roughly into groups according to the clinical manifestations and course of the disease and not according to the pathologic changes. The first group consists of cases of simple acute appendicitis in which we found the disease limited to the appendix or its immediate vicinity. In the second group, we found that the disease had spread beyond the appendix to the peritoneal cavity. Some of these patients were not operated on during the acute phase of the disease; they were treated according to the principles of deferred operation. A third group comprised patients entering the hospital in the late stage of the disease with a definite, palpable abscess. The fourth group consists of patients who were dying as they entered the hospital and are listed separately, as it is unfair to any method of treatment to include them.

The first group, listed under the heading of acute appendicitis, comprises 213 patients. In this group the disease had been present for an average of 22.5 hours. They were all operated on very soon after admission to the hospital. One patient died, the mortality rate being 0.46 per cent. Multiple hepatic abscesses developed in this patient from infected thrombi in the vessels of the meso-appendix. The average stay in the hospital was 8.2 days. These results emphasize the importance of early diagnosis and operation while the disease is limited to the appendix. The second group in which we made a diagnosis of diffusing peritonitis will be discussed later in the paper.

TABLE 2.—Analysis of Cases in Which Recovery Occurred with Deferred Operative Treatment

Number of Cases, 77	Number	Per Cent	Preoperative Days	Total Hospital Days
Subsidence without operation	29	37.6	...	13
Development of localized abscess	45	62.4	9.3	251
Abscess treated by appendectomy with drainage of abscess	32	41.5		
Drainage of abscess only	16	20.7		

The third group, comprising thirty-five patients, came for surgical treatment with a definite abscess and had been sick for an average of 10.1 days. The abscess was drained and the appendix removed when possible. Two patients died, a mortality rate of 5.7 per cent. One of these patients, a boy, aged 8 years, had a pulmonary abscess associated with an appendiceal abscess and died of a pneumococcal septicemia. A second boy, aged 16 years, was admitted with an enormous pelvic abscess which ruptured some hours before it was drained, causing death three days later. The average hospital stay was 22.7 days.

The fourth group consisted of three children, aged 3, 4 and 4; all were the victims of vigorous purging

and had been sick for three days. They entered the hospital unconscious and pulseless. One died before she was examined, another died in one hour, and the other died in three hours. They are not included in any treatment group as no treatment could have been of any avail, but they are included in the total mortality figures. They died because the diagnosis had been made too late and because they had been purged.

DEFERRED OPERATIVE TREATMENT

The second group, which includes the patients with a spreading peritonitis, comprises eighty-five patients (25.3 per cent of the entire series) for whom the deferred operative treatment was carried out. These patients had had appendicitis for an average of three and one-tenth days before entering the hospital. Our rule for selecting patients for this type of treatment is as follows: Every patient entering the hospital with acute appendicitis of forty-eight hours' duration or longer was seen by a senior surgeon and the question of the stage of the disease and the type of treatment were carefully considered. If it was felt that the disease was limited to the appendix or its vicinity, an immediate operation was performed; but if it was felt that diffusing peritonitis was present, the deferred operative treatment was chosen. Any patient with appendicitis of less than forty-eight hours' duration in whom it was thought that peritonitis might be present was also seen by a senior surgeon. In short, the deferred operative treatment was undertaken only after consultation with careful individual consideration of the patients.

The history, signs and symptoms of diffusing peritonitis are usually typical. There are observed the hippocratic facies, dehydration from vomiting, fever varying in degree but often rising to 104 F., rapid pulse and respiration rates, restlessness and a rigid diffusely tender abdomen and a high leukocytosis. Many variations occur, however, and at times it taxes the most experienced surgeon to diagnose the exact stage of the disease. We have been pessimistic enough always to prophesy that conditions are worse than seems probable from the external evidence. Undoubtedly some of the patients in whom we made a diagnosis of diffusing peritonitis had only a localized peritonitis that later developed a walled-off abscess or recovered without its formation.

The treatment carried out is essentially that advocated by Ochsner³ in 1892. The patient is put into a comfortable Fowler's position, heat is applied to the abdomen by an electrical pad or an electrical baker, and morphine is given in sufficient quantities to keep the patient free from pain and apprehension. The stomach is emptied by positive siphonage through a small indwelling duodenal tube introduced through the nose, and absolutely nothing is given by mouth. The urine and blood chemistry are studied. Physiologic solution of sodium chloride and 5 per cent dextrose solution are given alternately by continuous intravenous drip; at least 5,000 cc. is given daily to an adult; at least 1,500 cc. of urine should be secreted daily. No enemas are given and fluids are not administered by rectum. The gastro-intestinal tract is given as complete a rest as possible.

Usually within a few hours a favorable change is noted. The temperature and pulse rate fall, the vomiting ceases, the skin and tongue become moist and the abdomen becomes less rigid and tender. Distention of

the abdomen, if present, often subsides, but it may or may not reappear. With the complete rest given to the gastro-intestinal tract, distention did not usually become a troublesome symptom. In no case was it felt obligatory to do an enterostomy; this is in marked contrast to our previous experience with the same type of case, in which immediate appendectomy had been performed and in which we performed an enterostomy almost as a routine.

The progress of a typical reaction to deferred operation is seen in chart 1. The patient had been sick for three days with a characteristic history of acute appendicitis prior to admission to the hospital. He was first seen with a higher fever, rapid pulse and respiratory rate and a leukocytosis of 19,000, with generalized abdominal rigidity and tenderness. The response to treatment was striking. There was remarkable improvement in the symptoms just cited and a

Chart 1.—Progress of a typical reaction to deferred operation. Onset of symptoms three days before admission. Appendectomy and drainage of abscess on fourth day in the hospital.

corresponding improvement in the clinical symptoms. An abscess was detected on the sixth day of the disease, and the third day of treatment, and was drained on the following day. Convalescence was uneventful and the patient was sent home after fifteen hospital days.

Frequent, at least daily, examinations of the pelvis and abdomen must be made in anticipation of the development of an abscess. The average time in which the abscess was noted was seven days after the onset of treatment. The results of treatment are shown in table 2. Of the eighty-five patients treated in this manner, eight died, a mortality of 9.4 per cent. Of the seventy-seven who survived, twenty-nine, or 37.6 per cent, grew steadily better; the signs of the disease disappeared, no abscesses developed and they were discharged home on an average of thirteen days. In spite of the fact that no demonstrable abscess was found and that in no instance did an abscess drain spontaneously through the bowel, we feel certain that a peritonitis of

some degree was present. These patients probably had a peritonitis of relatively mild virulence, or the infected area was more effectually walled off.

We direct these patients to return for appendectomy in eight weeks and the great majority of them have undergone an appendectomy at about that time. In most instances, there still exists at that time both gross and microscopic evidence of recent severe infection and perforation. In forty-eight patients an abscess developed and an operation was performed in an average of nine and three-tenths days after admission to the hospital, or on the twelfth day of the disease. In thirty-six patients the abscess was localized in the region of the appendix in the right lower quadrant of the abdomen. In nine patients the abscess uniformly filled the pelvis. In three patients the abscess was in a retrocecal or paracecal position and there existed an associated subphrenic abscess. Localization of the infection usually begins to be obvious on the sixth or seventh day after institution of the treatment and can usually be felt by abdominal, rectal or bimanual palpation. The presence of diarrhea is almost pathognomonic of the formation of a pelvic abscess. Frequent roentgen studies of the chest

Eight patients died while undergoing the deferred operative treatment. A study of these is of interest and is shown in table 3. We feel that the first five patients were doomed with any form of treatment. Patient 1, a girl, aged 5 years, had the disease for ten days before hospitalization and was treated during this time for cystitis by forced fluids and bladder irrigations. She was dehydrated, profoundly septic and died four days after admission. Autopsy showed a diffuse general peritonitis. Patient 2, a boy, aged 8 years, entered the hospital with signs and symptoms of peritonitis. He was unconscious, had frequent convulsions and died on the fifth day of the disease. Autopsy showed him to have a well walled-off abscess in the right side of the pelvis but with a very large thymus and general evidence of a thymolymphatic constitution. Patient 3, a boy, aged 11 years, had received daily purges for a week and when first seen in the hospital was very septic and continued in a desperate state until death one week later. The autopsy showed a generalized peritonitis. Patient 4, a girl, aged 12 years, entered the hospital unconscious and had frequent convulsions until death.

No localizing signs were present and the diagnosis was in doubt until the autopsy showed a generalized peritonitis. Patient 5, an obese woman, aged 55, worked in the field on a farm for five days with daily catharsis during the progress of the disease. She was profoundly septic and pulseless and died in two days.

The last three fatal cases offer a different problem, and we feel that these patients might have recovered if our handling of them had been more skilful. It will be noted that drainage of an abscess either was performed late or was inadequate, as shown by the necessity of redrainage. Edema of the external genitalia developed in all three of these patients, and at operation large abscesses under tremendous tension were found which were not detected earlier in spite of frequent abdominal and

rectal examinations. Without being able to explain the exact mechanism of the production of the edema of the external genitalia, we have come to look on it as of great importance, signifying that there was a pelvic abscess under tension and probably one that had passed the optimal time for drainage.

In two cases recently, not included in the group of patients here under discussion, we have operated as soon as edema appeared, in spite of the fact that an abscess could not be palpated; in both instances abscesses were found and drained, and the patients recovered. Usually the presence of an abscess is easily detectable, but occasionally, as in the three fatal cases just mentioned, it may be a matter of great difficulty; the persistence of general signs of sepsis, abdominal pain, a rising leukocytosis and the presence of an abscess should lead to an assumption of the presence of an abscess, even though it cannot be definitely felt as a mass. Abscesses may be multiple and may require multiple drainage, although the formation of secondary abscesses is not as common in our experience in the patients treated by the Ochsner method as in those treated by immediate appendectomy and drainage. In the three cases mentioned in the preceding paragraph, drainage was instituted later than usual and all three

Chart 2—Leukocytosis in four patients with general peritonitis treated by delayed operation

must be made for comparative study of the diaphragm in order to make an early diagnosis of subphrenic abscess, which must always be suspected.

The behavior of the leukocyte count is of some interest in connection with development of the abscess. The leukocyte count of four typical cases is shown in chart 2. As can be seen, there was a steady drop in the leukocyte count for the first six days, corresponding to the fall in temperature and pulse and with improvement in the patient's general condition. This reaction, which is almost constant, probably indicates the time at which the generalized infection is disappearing or is being localized. It is at this time that the presence of an abscess should be suspected. As the abscess develops, the leukocyte count again rises. The location of the incision used and the type of operation performed varied. The incision was always made over the presenting point of the abscess, and the appendix was removed in thirty-two cases at the time of drainage of the abscess. In sixteen patients the abscess was simply drained. The appendix was always removed if it was accessible and if it could be removed without breaking the wall of the abscess; otherwise it was left to be removed at a later date.

cases required redrainage. It is probable that had we been more alert and performed drainage earlier, the occurrence of the secondary abscess and reoperation might not have been necessary. The proper management of these patients requires the utmost vigilance and taxes the experience and judgment of the surgeon to the limit.

TABLE 3.—*Analysis of Patients Dying with Peritonitis Treated by Deferred Operation*

Name	Sex	Age	Duration of Disease, Days	Purge	Hospital Day of Death	Operation	Comment
Case 1	♀	5	10	No	4th	No	Far advanced diffuse peritonitis; treated for cystitis before entrance
Case 2	♂	8	2	Yes	3d	No	Abscess well walled off; unconscIOUS; convulsions; thymolymphatic constitution
Case 3	♂	11	7	Yes	7th	No	Far advanced generalized peritonitis
Case 4	♀	12	2	Yes	2d	No	Unconscious; convulsions; septicemia
Case 5	♀	55	6	Yes	2d	No	Farm work prior to hospitalization; general peritonitis

As will be seen from our mortality table, most of the deaths occur in children. This opens the question of the applicability of the principle of deferred operation to them.

In table 4 is shown the mortality in the various clinical types of the disease as it occurs in the different age groups, with special reference to the young. The mortality in patients under 18 years was 6.3 per cent and in patients over 16 years it was 2.2 per cent.

In general it is true, as shown here, that the younger the child, the greater will be the mortality with any form of treatment. The disease is generally not recognized early because of the difficulty or impossibility of eliciting a history and because of the prevalent idea among mothers and some physicians that children are subject to abdominal pain of mysterious origin that can be cured only with a purge. The sooner the knowledge becomes widespread that infants and children are liable to the same organic diseases that affect adults, and that a child with abdominal pain is entitled to a physical examination before purging is done, the sooner will the child with appendicitis have the same chance of recovery as has the adult. All the children on whom we carried out the Ochsner treatment were much sicker than the members of the adult group. The mortality in children is high because of late diagnosis, home treatment with almost universal purging and, in addition, the anatomic and physiologic differences between young children and adults. The omentum, which plays such an important part in the defensive mechanism, is much less developed in children, and localization of infection is correspondingly less efficient and frequent. The young child tolerates the infection less well and his body chemistry is less stable than is that of the young adult.

The mortality of patients less than 16 years of age having general peritonitis and treated by this method was 12.5 per cent; this compares favorably with treatment by any other method and is better than our own results in this group treated by immediate operation. For the reasons we have enumerated, these patients are often in a desperate condition and offer the most difficult surgical problem in appendicitis. Without exception, we have treated them in exactly the same way as the adults, but they require infinitely more careful supervision and nursing care. Distention is much more common among children and is slower to subside. Although the deferred operative treatment is less efficient in children than in adults, any form of treatment is less efficient in children. We feel, therefore, that the principle of delayed operation should be applied to children with peritonitis. They so often come to the surgeon dehydrated and with acidosis; immediate operation only hastens an unfavorable outcome. By deferring operation even for a short time, the body fluids and body chemistry can be restored to normal, and they are then in a much better condition to withstand operation.

COMMENT

Surgeons have been urging early operation for acute appendicitis since it became recognized as a disease entity. There is no doubt of the soundness of this principle. We heartily subscribe to the dictum of immediate operation as soon as the diagnosis of acute appendicitis has been made. Also, we recommend operation in cases in which appendicitis is suspected; it is much better occasionally to remove an innocent appendix than to allow acute appendicitis to progress to its complications. However, to urge early operation for acute appendicitis is not the same as to urge immediate operation when the disease is no longer simple acute appendicitis but is complicated by a diffusing peritonitis.

* Death in three hours.

There exists a great diversity of opinion concerning the method of operative attack on patients with general peritonitis. Most surgeons advise removal of the appendix and drainage of the peritoneal cavity. Others advise removal of the appendix and closure of the peritoneum without drainage; thereafter the treatment is similar to the Ochsner method of treatment. Other surgeons simply drain the peritoneal cavity without removing the appendix; a very few surgeons still carry on an elaborate toilet of the peritoneal cavity with

wipings and irrigations. Jones⁹ recently reported a very low mortality in this type of patient after treatment by appendectomy and cecostomy. Our own experience with all these methods has been limited but, such as it was, has not been satisfactory.

Any type of operation carried out on a patient with a spreading peritonitis on the third, fourth or fifth day of the disease reduces the patient's ability to combat the infection, at least on theoretical grounds, presumably because the operation traumatizes the peritoneum before immunity is established. It is highly desirable to remove the appendix in every case in which it is a local focus of infection; when, however, peritonitis has begun to spread, its diffusion no longer depends on the presence or absence of the appendix. Once peritonitis has begun to spread, the peritoneum and abdominal cavity develop greater protective and reparative powers when they are not traumatized by operation. We feel that in a certain group of patients the protective function of the peritoneum can be encouraged and utilized by deferring operation until the immunity of the peritoneum has become well established.

Like any other surgical procedure, deferred operation has very distinct limitations. In the first place, the diagnosis must be certain, and, if doubt exists as between appendicitis and some other lesion for which immediate operation is desirable, one must not defer operation. Under no circumstances do we defer operation in cases of appendicitis associated with pregnancy, since the presence of the enlarged uterus prevents localization of the infection; because of this fact, operation in the pregnant woman should be performed on suspicion of the presence of appendicitis. No rule can be arbitrarily laid down as to the type of patient who should be treated by the method of deferred operation. We have found that every patient must be considered individually and the type of treatment finally chosen after it has been determined to the best of one's clinical ability that a spreading peritonitis is present.

The principle of deferring operation implies that an operation will eventually be performed. It is often difficult to choose the optimal time for operation, and a mistake may be serious. There should be no delay in draining an abscess once its presence is noted, or even suspected, because an enlarging abscess may rupture and reinfect the free peritoneal cavity. If this occurs, the result is often fatal. Secondary abscess in other locations may develop if the original abscess remains undrained. Deferred operative treatment is in no sense medical treatment. It must be carried on in a hospital by a surgeon who is prepared to operate at any time that the indications become clear. Few surgical problems present greater difficulties with respect to decision as to the optimal time for operation. In case an abscess does not develop, or in case the abscess is drained without removal of the appendix, the patient must be instructed to return for an appendectomy in from eight to twelve weeks. Observation has shown that the acute peritoneal reaction has disappeared by this time, making the operation technically easy, and if the operation is postponed for a longer time other acute attacks may supervene.

After an experience of three years with deferred operative treatment, we feel that it has definite advantages over the other methods of treatment with which

we are familiar and that it has a highly important place in reducing the mortality of peritonitis secondary to appendicitis.

SUMMARY

A study has been made of 336 patients with acute appendicitis treated in the University Hospital. The mortality was 4.1 per cent. In 213 patients, the disease was limited to the appendix, and immediate appendectomy was performed with a mortality of 0.46 per cent. In thirty-five patients there was an abscess present on admission to the hospital and immediate operation was performed with a mortality of 5.7 per cent. In eighty-five patients the appendix had ruptured and a diagnosis was made of spreading peritonitis. These patients were treated according to the principle of deferred operation as advocated by Ochsner; the mortality was 9.3 per cent. Among the seventy-seven patients who survived, the disease subsided without operation in twenty-nine and an abscess developed in forty-eight. The abscess was drained, with simultaneous appendectomy, in thirty-two patients, and simple drainage without simultaneous appendectomy was done in sixteen patients.

CONCLUSION

The treatment by delayed operation has an important part in the management of the late stages of acute appendicitis complicated by general peritonitis. Its use should be limited to this group of patients.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRs. GILE AND BOWLER AND
DRs. COLLIER AND POTTER

DR. ALTON OCHSNER, New Orleans: The measures emphasized by Drs. Collier and Potter are of the utmost importance: the absolute withholding of everything by mouth, allowing not even water, and the liberal use of morphine, not with the idea that it splints the bowel but because morphine, instead of inhibiting bowel activity, actually increases it. It doesn't increase peristalsis but it does increase the tone of the bowel. Patients with peritonitis do not die from the peritonitis as such. They die of their associated adynamic ileus, which can be largely prevented by increasing the tone of the intestine by liberal doses of morphine, and in this way the mortality rate from peritonitis can be definitely decreased. As every one knows, the mortality rate in appendicitis is increasing. My explanation of it is that these patients are coming into the hospital with a peritonitis, too late for the early operation and too early for the late operation, an axiom that was first sounded by Richardson. These patients should be treated conservatively by the use of heat to the abdomen, absolutely nothing by mouth, and large doses of morphine. As a result of the large doses of morphine, frequently their vital capacity is decreased. I try to combat the anoxemia by giving them oxygen. I feel that this is important. I agree with Drs. Collier and Potter that these patients should not be given enemas, because anything that will tend to increase the intestinal peristalsis will tend to break down the protective barrier, which is of such importance. I give nothing by rectum. Proctoclysis should not be given, because even though given slowly it tends to increase peristalsis, a condition that is not wanted. In my series the incidence of abscess formation has been less than in the series of Drs. Collier and Potter. Only about 30 per cent of my patients who have come in with a definite, palpable mass have developed abscesses. The explanation is that the mass which is palpable is an inflammatory one, consisting of the omentum and inflammatory exudate. This inflammatory process subsides without progressing to suppuration. In such cases the appendix should later be removed. In cases in which suppuration occurs it is important that incision and drainage be instituted as soon as suppuration has occurred.

⁹ Jones, E. S.: Appendectomy in Cases of Ruptured Appendix Associated with Diffuse General Peritonitis, *Ann. Surg.* 99: 640-649 (April) 1934.

DR. LE GRAND GUERRY, Columbia, S. C.: In 1,438 cases of recurrent appendicitis in my experience of more than thirty-two years there were no deaths. In 858 cases of acute appendicitis there was one death. This group includes the definite, acute cases of appendicitis up to the point of rupture. No case was included in this group in which there was gross perforation of the appendix. In the third group there were 484 cases of gangrenous, ruptured appendixes with three deaths. In a group of localized abscess cases of this size one would run the gamut of intraperitoneal suppuration. In group 4 there were ninety-four cases of gangrenous, ruptured appendixes with diffuse peritonitis. These patients were operated on immediately, with ten deaths, or a mortality of 10.64 per cent. In striking contrast to group 4 is group 5, with 135 cases of gangrenous, ruptured appendixes with diffuse peritonitis; there were two deaths, or a mortality of 1.4 per cent. The cases in this group were handled on the basis of deferred operation as given to me by Ochsner many years ago. My view is that the mortality rate in appendiceal surgery is largely determined by the way in which the cases in this critically ill group are handled, and that the principle of deferred operation is largely the solution of the problem. In a continuous, consecutive, unselected series of cases extending over a period of more than thirty years the mortality was around 0.5 per cent, a fact that in itself is most significant. I believe that to do a formal operation in this desperately ill group of patients is to invite disaster and an excessively high mortality rate. Deferred operation in the group of cases to which it is applicable should be regarded as the first step in the operative procedure and in no sense should be looked on as a means to evade operation. The whole force of the paper of Drs. Collier and Potter substantiates and proves the soundness of my contention. A separate group was made of ten cases in group 6, with three deaths, because the patients were moribund and they were the only ones in the entire series in which the appendix was not removed. The 423 cases in group 7, with one death, are presented to show the additional risk attached in removal of the appendix during the course of other operations. Only such appendixes are included in this group as gave unmistakable evidence of being diseased.

DR. C. F. DIXON, Rochester, Minn.: I feel that the total mortality rate in the experience recorded in both papers has been commendably low. I should like to reemphasize two points that were brought out: First, removal by an experienced surgeon of an acutely diseased, unruptured appendix is associated with practically no mortality rate; second, tragedies frequently occur when a patient with an acutely diseased appendix is given a cathartic. Careful study will show that the majority of patients who have ruptured appendixes, with general peritonitis, have taken some type of cathartic. Consequently it is this group of patients which gives the greatest concern. The report that Dr. Guerry published in 1926 is without question the finest that I know anything about. In it he reported from his personal experience 2,959 cases in which appendectomy had been performed in a period of twenty-five years, with a total mortality of 0.54 per cent. In 208 of these cases the appendix had perforated and diffuse peritonitis was present. In eighty-five of these 208 cases appendectomy was carried out immediately, with a mortality rate of 8 per cent. In the remaining 123 cases appendectomy was deferred for several days, with a mortality rate of only 1.6 per cent. Apparently it is the people of rural districts who succumb to peritonitis following perforated appendixes. It is possible that placing labels on cathartics dispensed, warning against their use in acute abdominal disorders, might help to lessen the perforations that occur in appendicitis. In a group of 523 patients on whom I operated consecutively because of acute appendicitis, 437 of the appendixes gave evidence of diffuse disease or gangrenous changes. In this series there were no deaths. In forty-eight cases the appendix had perforated, causing diffuse peritonitis, and abdominal drainage was instituted without an attempt to remove the appendix; there were five deaths, a mortality rate of 10.4 per cent. In the remaining thirty-eight cases localized abscess was present and extraperitoneal drain-

age was instituted, with a mortality rate of 7.7 per cent. After a review of the work of the authors who presented their papers today, as well as the work of Dr. Guerry, it would seem that removal of a perforated appendix in the presence of coexisting peritonitis is not indicated.

DR. R. J. BEHAN, Pittsburgh: The United States census reports state that the mortality from appendicitis was 9+ per hundred thousand of population in 1920 and it has gradually increased to 15+ per hundred thousand of population in 1932. How is this increasing mortality from appendicitis to be combated? An attempt to do so has been made by educating the public and the physicians to take cognizance of the early onset of pain in the right lower quadrant of the abdomen as possibly indicative of appendicitis and insistence that such patients be hurried to the proper person for diagnosis and treatment. The next consideration is, Is the virulence of appendicitis increasing? This is not known and if cases are worse probably nothing can be done about it. Therefore there remains the last part of that triad of possibilities, the correction of the inadequacy of treatment. Undoubtedly the treatment must be inadequate when the mortality is constantly increasing. I came here with well defined ideas in regard to certain forms of treatment. After listening to the authors I was a little in doubt, but nevertheless I think I should continue along the same way that I have been accustomed to do in the last six years. My mortality rate in forty-four cases of acute appendicitis associated with generalized diffuse peritonitis, from 1920 to 1928, was 50 per cent. In 1926 I gradually began to use alcohol inside the abdominal cavity. In 1930 it was used as a routine. My mortality has been reduced in fifty-four cases to three deaths, which is about 6 per cent. I have operated on every patient with diffuse suppurative peritonitis who entered my service, and by diffuse suppurative peritonitis I mean those cases in which when one opens the abdomen one finds free fluid (fibrinous exudate) present in the abdominal cavity, in some of them under such great tension that it oozes out of the incisional wound. I found *Bacillus coli* infection in about 31 per cent of these cases; in about 6 per cent I found a streptococcus (pure culture), and in the remaining cases I found a variety of organisms. The treatment that I give in these cases is about the same as is usually given in cases of peritonitis. The abdomen is rapidly opened under spinal anesthesia, a suction tube is placed inside the abdominal cavity, the pus is removed, and immediately I pour in alcohol and in a few minutes remove it by the suction apparatus. In one case in which there was a gangrenous appendix, with a necrosis of the cecum and with the abdomen diffused with the feces and the bowel contents, I used one gallon of alcohol in the intra-abdominal lavage. I have had no bad results. I found that they were absorbing the alcohol, and in tests of the blood I found that in one patient 50 mg. of alcohol per hundred cubic centimeters of blood was present.

DR. GEORGE A. HENDON, Louisville, Ky.: I think that the keynote for the treatment of peritonitis from whatever source should be a sustained continuity of effort. The problem of dehydration and starvation has been answered satisfactorily, both before and after operation, by a continuous process. The drainage of the intestinal canal should receive more consideration than it has. The drainage of the peritoneal cavity has engaged the most serious efforts for a long time. I think that, in the management of cases that have been described, enterostomy should be an essential ingredient of the program and not a subsequent incident. The plan that I use is to pass a drainage tube through the cecum at the situation of the appendix, through the ileocecal valve and a short distance into the ileum. I prefer to use the Pezzer catheter, because it has a bulbous extremity by which it is more readily maintained inside the intestine. There is another point, and that is the fact that there are serious blood dyscrasias to contend with. I have made routine blood examinations on these patients and have discovered invariably that there is a low calcium content, and by the administration of the calcium salts through venoclysis I have been able to raise the calcium content of the blood to

its normal figure and even beyond it. I have been impressed with the fact that the evidences of improvement almost invariably synchronize with the increase in the calcium. This is a point which I would like to have investigated from other sources in order that its importance may be estimated. The process of drainage from the upper end of the intestinal tract should also carry the ingredient of continuity, and the suction tube placed through the nose into the upper part of the intestinal tract should be so arranged that the drainage which follows does not have to be entrusted to the caprices of fortune; some effort in the way of a suction apparatus which works continuously and gently should be attached to insure the rapid and complete and continuous evacuation of the upper intestinal tract.

DR. F. F. LAWRENCE, Columbus, Ohio: That there has been an increase in the mortality of appendicitis in the past few years cannot be denied; that that increase is entirely due to the technic of handling the cases cannot be justly charged. The economic conditions of the last four or five years have operated in two ways: first, to urge the doctor to try to shorten hospital stay if possible or to avoid hospitalization if possible; the other, to handicap the patient so as to insist on avoiding hospitalization. Then there has been a reaction of public opinion to the oft repeated newspaper statements that every abdominal pain is considered an excuse for an appendectomy. The mortality and morbidity of appendicitis lies clearly in the delay in operating. Modern methods of training doctors in laboratory essentials and the failure to develop the use of the five senses have resulted in many delayed diagnoses and delayed operations, and consequently the patients frequently come to the surgeons moribund. The lack of benefits from the formerly called Ochsner treatment is due not to the method described by Dr. Ochsner but to its misuse. The attempt at the so-called fasting treatment for appendicitis, as Dr. Ochsner described it and as I have used it for thirty years most satisfactorily, does not permit the giving of medicine by mouth, does not permit the giving of even a teaspoonful of water by mouth, and it does not permit a distended stomach to remain so distended, but it means to empty the stomach with a stomach tube. There has been more or less swinging back to the idea that it is a crime to permit a poor human being to suffer a little bellyache, and consequently the use of morphine. There are three important reasons for the increased mortality: morphine, delayed diagnosis and operation, and misapplied Ochsner treatment. Of those three things which have to do with increasing the mortality, the delay in operation is the most important.

DR. FRED A. COLLIER, Ann Arbor, Mich.: I am glad that Dr. Lawrence spoke, because I began to see the light only about three years ago. He has seen it for thirty years. The use of alcohol in the abdominal cavity is new to me. I have, however, seen a great many other chemicals poured in. I recall that at one time tincture of iodine was popular in the hands of some surgeons, and I recall that ether was commonly used for this purpose, especially by the French surgeons. I must say I would have a good deal of trepidation about pouring a large amount of alcohol into the abdomen, but Dr. Behan has done it and I have not, and his mortality figures are very low. I think Dr. Hendon is right to insist on fluids. We owe him a debt of gratitude for the method he has devised for the continuous intravenous administration, which we use in all cases. I am gratified that he believes in the siphonage treatment, that is, the inlying duodenal tube, which I have casually mentioned. It was hearing a paper by Dr. Guerry that convinced me I should try this method of treatment. I think no one has had the results in the treatment of peritonitis that Dr. Guerry has had. One can sum up the entire situation by saying that if we would no longer purge patients, if we would make our diagnosis early and insist on hospitalization and operation, this entire problem would be solved because we would have only appendicitis to treat and we would never get these cases of general peritonitis that we have been talking about today.

SODIUM FERROCYANIDE AS A CLINICAL TEST OF GLOMERULAR EFFICIENCY

PRELIMINARY REPORT

EDWARD J. STIEGLITZ, M.D.

AND

ALVA A. KNIGHT, M.D.

CHICAGO

Despite the almost innumerable tests of renal function that have been suggested, we feel justified in presenting a new procedure because of its distinct advantages. The essential criteria of a practical functional test of clinical value are: (1) simplicity, (2) safety, (3) specificity for the structures or functions studied, (4) creation of stress conditions, and (5) uniformity of normal results. These criteria are all fulfilled by sodium ferrocyanide, as here applied. The procedure and calculations are simple, the substance has proved entirely nontoxic, it places stress on the kidneys, for it is a substance foreign to the body, and the variation in excretion in normal persons is relatively slight.

Ferrocyanide salts have the unique characteristic that, so far as its known, they are excreted solely by the glomeruli. The work of Marshall¹ and Marshall and Grafflin² with the renal secretion in aglomerular fish revealed that ferrocyanide is not eliminated at all by these fish, or in but extremely minute traces. The more recent studies of Gersh and Stieglitz³ with mammals convincingly demonstrate that ferrocyanide salts are eliminated by the glomeruli. There was no evidence whatever of tubular secretion. The rate of elimination appeared to be wholly independent of the rate of water excretion. It was because of these previous studies, indicating an extraordinary glomerular specificity, that we have attempted to apply this substance to clinical investigation of glomerular efficiency.

METHOD

Sodium ferrocyanide has been used in all instances. Potassium ferrocyanide is often toxic. The Abbott Laboratories generously prepared for us sterile ampules of dry sodium ferrocyanide containing 0.5 Gm. of the hydrated salt per ampule, or about 0.25 Gm. of the anhydrous salt. Extreme care is required in the preparation of these ampules, for the substance must be sterilized without heat, which tends to break down the ferrocyanide and liberate free cyanide ions. The Abbott Laboratories at first experienced difficulty because of spore-bearing organisms, but in using carefully synthesized sodium ferrocyanide this difficulty was overcome. Ferrocyanide salts may be decomposed by the acid of the stomach, if taken orally, but on slow intravenous injection of the sodium ferrocyanide no evidence of any toxic effect has been observed and none is to be anticipated.⁴

Our technic has been to dissolve completely the contents of one ampule (0.25 Gm. of the anhydrous salt) in 10 cc. of sterile distilled water and administer this by

From the Department of Medicine, Rush Medical College, the University of Chicago.

Read before the Section on Pathology and Physiology at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 15, 1934.

Grateful acknowledgment is made to the Chemical Foundation for its aid in this work, received through the Julius Stieglitz Fund for Research in Chemistry Applied to Medicine.

4. Sollmann, Torald: Personal communication to the authors.

slow intravenous injection. Following this, specimens of urine are collected and analyzed for their content of ferrocyanide. Various time intervals have been tried, but we have found that four specimens collected at 30, 60, 120 and 180 minutes after the injection yield the maximum of information.

The Titration.—The titration is carried out with a quantitative copper sulphate solution.⁵ This is made to contain 0.4 per cent of copper sulphate (0.004 Gm. per cubic centimeter). The content of copper is determined exactly by electrolysis. Before titration the specimens are acidified with concentrated sulphuric acid. Copper ferrocyanide is an insoluble red salt but is less insoluble than the well known Prussian blue. This fact is used in determining the end point of the titration. Drops of concentrated ferric chloride solution are placed on a tile and as the titration proceeds a drop of the unknown solution is placed in contact with the ferric chloride. If free ferrocyanide is present an immediate formation of Prussian blue occurs; if all the ferrocyanide has been precipitated as cupric ferrocyanide, a distinct delay occurs in the appearance of this blue color

TABLE 1.—Chemical Reaction

Molecular weight of $\text{Na}_4\text{Fe}(\text{CN})_6 = 304.08$

Molecular weight of $\text{CuSO}_4 \times 2 = 319.26$

$$\begin{array}{rcl} \text{Therefore,} & \frac{304.08}{319.26} & = \frac{X}{0.004} \\ & X & = 0.0038 \end{array}$$

Therefore, 1.0 cc. CuSO_4 precipitates exactly 0.0038 Gm. $\text{Na}_4\text{Fe}(\text{CN})_6$

Example: Dose of $\text{Na}_4\text{Fe}(\text{CN})_6 = 0.25$ Gm.

15 cc. of CuSO_4 used to reach end point

$0.0038 \times 15 = 0.057$ Gm. $\text{Na}_4\text{Fe}(\text{CN})_6$

$$\frac{0.057}{0.25} = 22.8\% \text{ of total injected dose}$$

on the tile. The more insoluble ferri-ferrocyanide slowly replaces the slightly more soluble cupric ferrocyanide. The end point is therefore read when the appearance of blue is delayed appreciably (five seconds), and the number of cubic centimeters of copper sulphate required is noted.

Calculations.—The chemical reaction that occurs is represented in table 1.

If hematuria exists during the period of ferrocyanide elimination the method of titration must be modified, for the sulphuric acid apparently liberates sufficient ferric ions from the hemoglobin to precipitate Prussian blue and thus prevent the formation of the red cupric ferrocyanide. This difficulty is readily avoided by determining the volume of the specimen of urine, bringing it to a quick boil, which precipitates the protein, and then filtering it. A measured quantity of this filtrate is then acidified with concentrated sulphuric acid and titrated in the usual way, the results being corrected to the original volume of the specimen.

RESULTS

The majority of our observations were made in the medical service of Drs. L. C. Gatewood and A. A. Knight at Cook County Hospital. We have also studied the excretion curves of a number of healthy students. Our primary objectives in this preliminary investigation were to determine the degree of variation in excretion

in the normal individual and to evaluate the excretion curves in two or three common disease states. In almost all instances the excretion of phenolsulphonphthalein⁶ was also observed, the same time intervals being used as for the ferrocyanide excretion. Because of the crowded and hurried conditions at the Cook County

Chart 1.—Excretion curves for sodium ferrocyanide and phenolsulphonphthalein in fifty normal persons. Solid lines indicate averages, broken lines the extremes of variation: dashes for ferrocyanide and dots and dashes for phenolsulphonphthalein; A, phenolsulphonphthalein; B, sodium ferrocyanide.

Hospital, extensive control with other renal function tests, such as the urea clearance test and the Mosenthal test, was not undertaken.

Chart 1 reveals the average normal excretion curve of sodium ferrocyanide, as contrasted with the excretion

curve of phenolsulphonphthalein, in fifty presumably normal individuals, the graph being recorded as percentage of the substance eliminated. The broken lines indicate the extreme degrees of variation noted. It is obvious that, although there is a moderate degree of individual variation in ferrocyanide elimination, this

variation is distinctly less than that observed in the phenolsulphonphthalein excretion.

In eleven cases of hypertensive arterial disease with adequate cardiac efficiency and no urinary evidence of renal injury, the average excretion of phenolsulphonphthalein is slightly diminished under the normal average, but the ferrocyanide output is quite conspicuously reduced (chart 2). For example, at sixty minutes the normal phenolsulphonphthalein excretion was 50 per cent, and the average in the hypertensive patients 38 per cent (a fall of 24 per cent); with the ferrocyanide

artery and producing both marked hypertension and renal impairment are of great interest. Further studies of the ferrocyanide excretion in hypertensive disease are needed and are contemplated.

In eight cases of cardiac decompensation, both the ferrocyanide and the phenolsulphonphthalein excretion are much impaired; the former more so than the latter (chart 3). It is evident that impairment of renal circulation markedly affects the excretion of the salt. It has been claimed^{1a} that renal function is not impaired by cardiac decompensation; such a conclusion is invalid.

excretion the normal was 20 per cent at sixty minutes and 10.1 per cent in the hypertensive patients (a fall of 50 per cent). It is thus clear that the excretion of ferrocyanide is more sensitive to changes in the glomerular circulation. This is to be expected in view of the glomerular elimination of the ferrocyanide and the tubular secretion of the phenolsulphonphthalein.⁷ It is thus evident that in the hypertensive patient the glomerular efficiency is notably impaired. This is contrary to the conception⁸ that arterial hypertension is a protective mechanism to insure an adequate and improved glomerular circulation. The recent studies of Goldblatt and his collaborators⁹ in slowly clamping the renal

The results obtained in fourteen cases of distinct nephritis are best presented in tabular form (table 2). In seven cases none of the injected ferrocyanide could be reclaimed in the urine. In the others, the excretion was most severely impaired. In one instance of glomerulonephritis in a young girl, a distinct increase in the impairment was detectable over a period of one month (case 76). Unfortunately, during our period of study, we have seen no case of true nephrosis.

COMMENT

Sodium ferrocyanide offers a number of distinct advantages over other test substances for renal functional studies. It has previously been experimentally

demonstrated that ferrocyanide salts are excreted wholly by the renal glomeruli,¹¹ whereas phenolsulphonphthalein is excreted by the convoluted tubules, as are ferric salts.¹² Uric acid is largely, if not solely, removed by the glomeruli.¹³ The routes of renal secretion of urea and creatinine are still somewhat uncertain. Urea is probably secreted by the convoluted tubules,¹⁴ and there is evidence, as yet not fully convincing, that creatinine is eliminated by way of the glomeruli.¹⁵ If this is true, further studies should reveal a very close parallelism between ferrocyanide excretion and the creatinine clearance test.¹⁶ Lassen and Husfeldt¹⁷ have very recently reported that in normal young men a fall in arterial tension induced by spinal anesthesia greatly decreased the glomerular filtration, although the tubular concentration was unimpaired. In acute hypotension to levels below the osmotic pressure of the blood colloids, ferrocyanide excretion ceases in rabbits.³ Although it has been shown that in hypertension the blood flow through the kidneys is more rapid than normal,¹⁸ the total glomerular efficiency is diminished. This may be attributed to the fact that injury to the glomeruli interferes with filtration more than with the free flow of blood.¹⁹

Chart 3.—Excretion curves for sodium ferrocyanide and phenolsulphonphthalein in eight patients with congestive cardiac failure.

We cannot discuss here the involved problems of the mechanism of renal secretion and the relation of this mechanism to the state of the circulation, but we feel that it is justifiable to point out that the ferrocyanide test offers a somewhat new and most promising method of approach to some of these problems. It is notable that in hypertensive arterial disease this glomerular function test reveals more extensive impairment than does the phenolsulphonphthalein test. Hypertension appears to diminish rather than enhance glomerular function, at least when the diastolic tension is raised through arteriolar hypertonia.²⁰ In one instance of aortic regurgitation with a huge pulse pressure (arterial tension of 220 systolic and 40 diastolic) the excretion of ferrocyanide was considerably increased over the normal: 38.9 per cent at sixty minutes and 50.7 per cent

at 120 minutes. Although it is impossible to draw any conclusions from this single instance, it is an interesting observation and suggests further study.

The spread of variation in excretion of ferrocyanide is less than that observed with phenolsulphonphthalein. This is of considerable importance, for uniformity of the normal response is a vital criterion of an effective functional test. Fractional readings at 30, 60, 120 and 180 minutes reveal delay in excretion, as they do with phenolsulphonphthalein,²¹ and are therefore more significant than the total output after three hours.²² The secretion of phenolsulphonphthalein is notably affected by diuresis and also by hepatic injury,²³ whereas our previous experimental work revealed essentially identical elimination of ferrocyanide in dehydrated animals and in those in which a water diuresis was induced.³ The renal concentration tests are probably the best guides to tubular efficiency,²⁴ but the ferrocyanide test reveals glomerular impairment.

CONCLUSIONS

1. Sodium ferrocyanide, in doses of 0.5 Gm. of the hydrated salt (0.25 Gm. of anhydrous sodium ferrocyanide) has been used in more than 100 individuals for the purpose of studying the glomerular efficiency.
2. It has proved entirely nontoxic in this dosage, when slowly administered intravenously.
3. The normal secretion curve is characteristic and shows but relatively little spread of variation. This variation is less than that of phenolsulphonphthalein excretion.
4. So far as is known, ferrocyanide salts are excreted solely by way of the glomeruli.
5. In hypertensive arterial disease the excretion of ferrocyanide is considerably retarded, much more so than the phenolsulphonphthalein elimination.
6. In congestive heart failure both the phenolsulphonphthalein and the ferrocyanide elimination are impaired.
7. In known glomerulonephritis the excretion of sodium ferrocyanide is either nil in severe cases or else very much reduced.
8. This test offers notable potentialities of clinical usefulness, since it is specific for the glomeruli, is safe, is simple of execution, and is quite constant in the normal.
9. In physiologic investigations of the mechanism of renal secretion the procedure should also prove of considerable value.
10. Much further work is required before the full significance and import of these studies are understood. We hope that this preliminary report may encourage others to extend and amplify this work; it has been our object merely to present a new method and to point out some of its potentialities.

other ferrocyanides, such as potassium, magnesium and calcium, is excreted entirely through the glomeruli, the tubules having nothing to do with the secretion. As far as I know, it is the only substance in which this has been proved. Perhaps the most interesting implications of these clinical applications are the physiologic. After all, this is a section on physiology and pathology, so the physiologic implications warrant emphasis. That observation in a patient with a large pulse pressure in aortic regurgitation of an excretion of almost twice the normal amount at stated time intervals, I think, makes one stop and think with regard to the mechanism of glomerular activity. There has been a good deal of argument as to whether hypertensive disease is or is not a protective mechanism. It has been claimed by some that in the hypertensive patient a definite elevation of blood pressure is required to maintain an adequate renal circulation. I myself am convinced, not from this alone but from other observations, that that is an entirely erroneous conception, that the renal circulation and the renal efficiency are markedly impaired during the hypertensive state. With a lower blood pressure in the same individual there is better and more effective circulation, better and more effective function. As yet we have not made any extensive observations sufficient to warrant reporting on the ferrocyanide function of the secretion prior to therapy in hypertension and after reduction of the arterial tension. We feel that that warrants energetic study. Apparently, from these preliminary studies, it is the diastolic hypertension which apparently impedes glomerular efficiency rather than the systolic. We have here, in my opinion, a tool with which to carry out such investigation.

THE ADRENAL CORTICAL HORMONE

EXPERIMENTS WITH A COMMERCIAL ADRENAL EXTRACT (ESCHATIN)

J. M. ROGOFF, M.D.
CLEVELAND

The relatively large number of articles concerning the adrenal¹ "cortical hormone" that have been published during the past five or six years may lead clinicians to believe that such a hormone has been actually isolated and is available as an effective remedy for treatment of Addison's disease, so-called hypo-adrenalism, and a number of conditions that have no known relationship to the adrenal glands. I am impressed with the lack of proportion between the volume of literature on the subject and the substantial experimental work that it represents. Crude extracts, the composition of which is not known and which contain substances other than the indispensable product of the adrenal cortex, have been extensively used in various experiments from which deductions of far reaching physiologic and clinical significance have been readily made. Reports have been published on alleged remarkable beneficial influence of such extracts in the treatment of Addison's disease and a number of other diseases. Recently, a large commercial manufacturing drug firm has marketed, for general distribution as a therapeutic agent, a product represented as a physiologically tested extract of the adrenal cortex. The experimental tests to be reported in the present communication are concerned with this extract (Eschatin, Parke, Davis & Co.).

Experience gained from many years of constant research on the adrenal glands leads me to the belief that, in the recent apparent race for priority of publica-

tion or scientific achievement the goal has been overreached. Conservative physiologists and physicians will readily agree that critical analysis of the accumulated literature reveals little or no substantial progress beyond the basic fact, which was conclusively demonstrated for the first time about nine years ago by the late G. N. Stewart and myself, that the adrenal cortex stores an indispensable hormone which is present in certain extracts made from the gland and which, when administered to completely adrenalectomized animals, is capable of materially prolonging life and ameliorating symptoms of adrenal cortical insufficiency. The adrenal cortical hormone has not yet been isolated in pure form. Nor is it always possible to obtain it free from undesirable, sometimes injurious, substances in extracts made from the gland. It may therefore be considered rather premature to produce such extracts commercially, for general distribution, to be employed by parenteral administration to human beings.

Demonstration of adrenalectomized animals, some of which were benefited by administration of cortical extract, was given by Rogoff and Stewart in 1925, during meetings of the American Physiological Society. A preliminary report was published in 1927.² Further reports were made at the meeting of the American Physiological Society in 1928 and at the thirteenth International Physiological Congress, held in Boston in 1929. It was announced that active material could be extracted by various lipid solvents, including alcohol, acetone, petroleum ether, benzene and ether, and by selective use of combinations of these. The statement was repeatedly made that the most active preparations were obtained by initial extraction with alcohol and that the final product can be obtained in aqueous solution. Since 1926, numerous publications have appeared in various journals reporting similar results.

Shortly after Stewart and I demonstrated the beneficial influence of adrenal cortical extracts on the survival of adrenalectomized dogs, Hartman and his collaborators³ reported the preparation of an alleged potent extract by means of salt precipitation. We were unable to interpret their results as demonstrating potency of their extracts. A number of years previously we had made unsuccessful attempts to "salt out" the active material from extracts of the adrenal. However, since Hartman and his associates recommend iso-electric precipitation, which was not included in our earlier attempts, we carefully repeated the experiments under the conditions described by these workers. We were unable to obtain products that were capable of prolonging life in adrenalectomized animals beyond the maximum survivals of our untreated control animals.⁴ After Swingle and Pfiffner⁵ published results that confirmed the reports by us that the active material of the adrenal cortex can be obtained by extraction with lipid solvents, Hartman discarded his salt precipitation method and has since then employed lipid solvents in the preparation of adrenal extracts.

1. The name "suprarenal" is appropriate only when referring to the gland in human beings and, perhaps, monkeys. In laboratory animals "adrenal" designates, more correctly, these organs. Since the name "adrenal" may also be properly employed in cases in which the gland rests above the kidney, I have preferred to use it, throughout this article, instead of suprarenal.

In the preparation of extracts by Swingle and Pffner and by Hartman and his co-workers, they employed very much larger amounts of gland substance per unit of final product than was employed by us. They also administered much larger doses of their products in their experimental work. Since we sometimes observed toxic action as well as beneficial influence of some extracts, it appeared probable that their practice might be disadvantageous. From a practical therapeutic standpoint their procedure presents the serious question of adequate supply of glandular material. According to their published reports it may often require up to 2 Kg. or more of adrenal glands per day to treat a single patient. Since we were able to obtain effective preparations by using much smaller amounts of gland material, it seemed desirable to make some comparative tests under our laboratory conditions and standards. It was not possible, however, to obtain their extracts for this purpose.

In our earlier experiments, dosage was arbitrarily determined on the tentative assumption that "interrenalin," the indispensable hormone of the interrenal gland (adrenal cortex), is probably liberated at a rate comparable with the rate of secretion of epinephrine from the chromaffin body (adrenal medulla). On this basis the amount of cortical hormone required each day for a cat of average size and in relation to the amount of epinephrine stored in the medulla would be present in an extract corresponding to approximately the amount of cortex representing 1 Gm. of whole adrenal. Since administration of extracts was made only once or twice daily and since not all the hormone may be expected to have been extracted from the cortex, our extracts were made to contain from two to three times the aforementioned theoretical value, and the actual dosage averaged approximately 1 Gm. of cortex per kilogram of body weight daily for completely adrenalectomized animals. Doses representing considerably less cortex were found effective in prolonging life in some dogs. At first, concentration of the extracts was employed so that 1 cc. was equal to 1 Gm. of cortex. Later, when we discovered the beneficial value of administration of physiologic liquids in adrenalectomized animals, some extracts were made so that 1 Gm. of adrenal cortex was contained in 10 cc. of extract. This permitted obtaining the combined effects of the cortical hormone and physiologic solution of sodium chloride, proving more effective in ameliorating symptoms and prolonging life. Indeed, this was the basis of the treatment of Addison's disease in my published report.⁶ However, the relatively crude extracts were not always obtained entirely free from undesirable impurities and occasionally yielded toxic manifestations when introduced parenterally. As repeatedly stated, this convinced me that until a product of known purity can be obtained readily it is dangerous to employ the extracts at present available by parenteral administration, especially by the intravenous route in human beings. Accordingly, I modified the process so that the final product is preserved in glycerin, for oral administration in adequate dosage. Thus far it is evident that not only is the use of this product free from the dangers of parenteral administration but it has proved to be decidedly more effective by mouth in the treat-

ment of Addison's disease⁶ than was found by others who employed their extracts parenterally. In reference to parenteral, especially intravenous, administration of available cortical extracts, it is pertinent to quote the following from the report of a special committee of the Council on Pharmacy and Chemistry of the American Medical Association:⁷

While recognizing and urging the value of intravenous therapy under appropriate conditions, it is equally important to emphasize the fact that the injection of any foreign substance directly into the human blood stream is always a serious undertaking. There are many conditions in which the risks inherent in intravenous therapy may greatly outweigh the real or supposed advantages which are claimed for the procedure. This is particularly likely to be the case with the more or less potent drugs. There is also a growing tendency on the part of many to resort to intravenous injection under conditions in which it is of dubious value, if not potentially harmful.

Since the Swingle and Pffner product has become available commercially, I obtained a sufficient supply, on the market, for a preliminary series of tests. A more extensive series of experiments was rendered impossible by conditions beyond my control. Nor was it possible at this time to undertake to repeat in detail some of the work reported by Swingle and Pffner. Two lots of Eschatin were purchased, one bearing the number 2984309 and the other 2989478. The physiologic criterion for potency of an adrenal cortical extract, established as the standard in our laboratory, is its capacity to prolong life of completely adrenalectomized animals beyond the maximum found in a large series of untreated adrenalectomized control animals. Since there is no essential difference between the process employed by Swingle and Pffner and that employed by us, except in the quantity of adrenal cortex represented in a cubic centimeter, some tests were made to determine the efficacy of Eschatin in prolonging life of adrenalectomized cats when the extract was administered in doses comparable with the maximum dose found adequate to prolong life in the experiments of Rogoff and Stewart. Other experiments were performed to test the value of Eschatin in relieving the symptoms of acute adrenal insufficiency, employing large doses, comparable with those used by Pffner and Swingle in their report on the revival of cats prostrate from adrenal insufficiency.⁸ In the first case the Eschatin was so diluted with physiologic solution of sodium chloride so that 1 cc. was equal to 3 Gm. of cortex, based on the statement of the manufacturer that each cubic centimeter of their product represents 30 Gm. of cortex (i. e., 1:10 dilution). This was administered in doses of from 1 cc. to 1.5 cc. daily in cats following adrenalectomy. No evidence of prolongation of life was obtained in those animals that received the extract daily nor was there any evidence of revival from prostration or improvement from acute manifestations of adrenal insufficiency when large dosage was administered after the onset of symptoms. In more than one animal there was evidence of toxic influence of the material. The results of these experiments are illustrated in the following condensed protocols:

CAT 1.—Female, weight 2.5 Kg. Left adrenal excised Dec. 1, 1932. Right adrenal excised Jan. 17, 1933. Intravenous injection of 1 cc. (= 3 Gm. cortex) Eschatin daily beginning January 18. The animal progressively declined and was found dead on the morning of January 22.

Med.*, 1930, p. 7; Diagnosis and Treatment of Addison's Disease, *Canadian M. A. J.* 24: 43 (Jan.) 1931; Addison's Disease: Further Report on Treatment with "Interrenalin" (Adrenal Cortical Extract), *J. A. M. A.* 99: 1309 (Oct. 15) 1932.

CAT 2.—Female, weight 2.72 Kg. Left adrenal excised Dec. 1, 1932. Right adrenal excised Jan. 17, 1933. Intravenous injection of 1 cc. (= 3 Gm. cortex) Eschatin daily for a week beginning January 18, then 1.5 cc. for three days. On the eighth day the animal refused food, on the tenth day became apathetic and asthenic and was found dead on the morning of January 28.

CAT 3.—Female, weight 2.42 Kg. Left adrenal excised Dec. 1, 1932. Right adrenal excised Jan. 18, 1933. The animal was in excellent condition until the eighth day, when she ate only part of her meal. On the ninth day she ate about half of her usual meal and on the tenth day she refused food, was asthenic and apathetic. At 11:30 a. m. an intravenous injection of 10 cc. (= 300 Gm. cortex) Eschatin, undiluted, was administered. From ten to fifteen minutes after the injection the cat had a convulsion which was so violent as to cause her to turn a backward somersault. This was followed by coma for five or six hours. In the evening she was able to sit up but was quite wobbly and in a stupor. January 29, at 8:30 a. m., she was found in deep coma and died while preparations were being made for another injection.

CAT 4.—Male, weight 2.7 Kg. Right adrenal excised Dec. 2, 1932. Left adrenal excised Jan. 17, 1933. Intravenous injection of 1 cc. (= 3 Gm. cortex) Eschatin daily for nine days beginning January 18 and 1.5 cc. for two days thereafter. The animal was in excellent condition for a week and then seemed somewhat less alert but still eating quite well for three days. January 28 he became apathetic and refused food; on this date his weight was 2.5 Kg. January 29, in the morning the cat was in deep coma; at 9:35 a. m. he had a convulsion and died at 9:40.

CAT 5.—Male, weight 3.21 Kg. Right adrenal excised Dec. 2, 1932. Left adrenal excised Jan. 17, 1933. Intravenous injection of 1 cc. (= 3 Gm. cortex) Eschatin daily for seven days beginning January 18 and 1.5 cc. for three days thereafter. The animal was in excellent condition for six days and on the seventh day showed some signs of asthenia and ate only part of a meal. From then on all food was refused and on January 28 the animal was quite apathetic; 5 cc. (= 150 Gm. cortex) Eschatin, undiluted, was administered intraperitoneally in the morning. At 6 p. m. there was no change in the animal and milk was refused. Weight 3.1 Kg. The animal was found dead the morning of January 29.

CAT 6.—Male, weight 2.32 Kg. Right adrenal excised Dec. 2, 1932. Left adrenal excised Jan. 18, 1933. Cat remained in excellent condition for five days. On January 24, he refused food but was not at all asthenic or apathetic. At 4 p. m. intravenous injection of 5 cc. (= 150 Gm. cortex) Eschatin, undiluted, was given. On January 25, the condition was unchanged, and he refused all food; intravenous injection of 5 cc. (= 150 Gm. cortex) Eschatin, undiluted. January 26, took a taste of salmon but refused any more food; subcutaneous injection of 5 cc. (= 150 Gm. cortex) Eschatin, undiluted. January 27, cat seemed limp, staggered on walking, refused all food; intravenous injection of 5 cc. (= 150 Gm. cortex) Eschatin, undiluted. January 28, 9 a. m., weight was 2.1 Kg.; comatose; dead at 9:30 a. m.

CAT 7.—Male, weight 2.72 Kg. Left adrenal excised Jan. 20, 1933. Right adrenal excised February 2. Cat was in good condition for six days. On February 9 and 10, the animal ate only part of his meals and showed some stiffness in hind legs and an unsteady gait. February 11, 8:30 a. m., asthenic and partly comatose but easily aroused; subcutaneous injection of 5 cc. (= 150 Gm. cortex) Eschatin, undiluted; 9:30 a. m., unchanged; 10 o'clock, deeper coma; 10:15, died.

CAT 8.—Male, weight 1.92 Kg. Left adrenal excised Jan. 20, 1933. Right adrenal excised February 2. Cat was in excellent condition until the fifth day, when the animal did not eat and showed some stiffness in hind legs on walking but was not apathetic; at 9:15 p. m., subcutaneous injection of 5 cc. (= 150 Gm. cortex) Eschatin, undiluted. February 8, took a taste of salmon but ate no more; seemed a bit less stiff in legs. February 9, in the morning, lethargic and quite wobbly; partly comatose; 10 a. m., subcutaneous injection of 5 cc. saline solution; at 11 o'clock, cat was decidedly more alert, appeared stronger and was able to stand and walk a few steps though wobbly, but this was not possible before the injection of saline.

The animal remained perfectly conscious; at 3 p. m. showed signs of somnolence. At 9 o'clock, more lethargic but perfectly conscious. February 10, 12:30 a. m., comatose; prepared to give injection of Eschatin and when cat was picked up a spastic convulsion occurred followed by another one in which it died.

CAT 9.—Female, weight 1.1 Kg. Feb. 3, 1933, ligation of blood vessels of both adrenal glands. The animal was in good condition for about a week but at no time since the operation did she eat her full meal. On February 9, some stiffness developed in the hind legs. On February 11, refused all food, asthenic and somnolent but completely conscious; 5:30 p. m., subcutaneous injection of 4 cc. (= 120 Gm. cortex) Eschatin, undiluted. February 12, found dead in the morning.

CAT 10.—Male, weight 3.3 Kg. Feb. 3, 1933, ligation of blood vessels of both adrenal glands. The animal was in good condition until February 23, when food was refused for the first time but he was not asthenic or apathetic. February 24, animal became apathetic and wobbled when walking; 4:15 p. m. intraperitoneal injection of 6 cc. (= 180 Gm. cortex) Eschatin, undiluted; 8:45, more asthenic, intraperitoneal injection of 5 cc. (= 150 Gm. cortex) Eschatin, undiluted. February 25, in the morning, condition unchanged, refused all food; at noon given intraperitoneal injection of 5 cc. (= 150 Gm. cortex) Eschatin, undiluted; 6 p. m., condition unchanged, intraperitoneal injection of 5 cc. (= 150 Gm. cortex) Eschatin, undiluted; 6:30, more apathetic, weight 2.85 Kg. February 26, in the morning animal found dead.

CAT 11.—Male, weight 2.12 Kg. April 26, 1933, ligation of blood vessels of both adrenal glands. The animal remained in good condition with occasional symptoms of moderate adrenal insufficiency until May 31, when he refused food but later in the day lapped a few teaspoonfuls of milk. There was also a beginning unsteadiness in gait. June 1, decidedly wobbly and apathetic; 12:10 p. m., given intravenous injection of 6 cc. (= 180 Gm. cortex) Eschatin, undiluted; at 12:15, the cat emitted a yell, muscular twitchings and extensor rigidity developed in the legs, it was unable to raise its head and it seemed bordering on coma; 12:30, deep coma; 12:50, died.

It would have been desirable to include a larger number of cats in the tests with the Eschatin diluted to represent 3 Gm. of cortex per cubic centimeter. The expense of the material and other conditions, as already indicated, did not permit this to be done. Since there was not the slightest indication of prolongation of life in any of the animals, however, it is fair to assume that the extract was not as potent as any of the earliest products that Stewart and I prepared. Indeed, the evidence shows that Eschatin is totally ineffective when judged by the criterion of Pfiffner and Swingle⁸ regarding its value in "the revival of cats prostrate from adrenal insufficiency." None of the cats tested derived any benefit from the extract, although one received the equivalent of 630 Gm. of cortex in two days, another 300 Gm. in one day, and a third 600 Gm. in four days. In two instances, cats 3 and 11, there was evidence of decided toxicity following the administration of Eschatin. It may be pointed out that Cleghorn⁹ reported the presence of significant amounts of histamine, and Eagle⁹ of choline, in similarly prepared adrenal cortical extracts. It is extremely surprising to have obtained such completely disappointing results, in view of the remarkable effects reported by Pfiffner and Swingle. At any rate, from the results of the tests made in these experiments the commercial extract does not seem to qualify as a "physiologically tested" product, and the evidence of toxicity renders it unsuitable for parenteral administration in human beings. In a normal individual and two patients with Addison's disease, serious reactions from administra-

tion of commercial extract of adrenal cortex were reported and attributed to the presence of protein (10 mg. per hundred cubic centimeters) and certain phenolic decomposition products of epinephrine in the extract.¹⁰

It is certain that in some of the experiments reported in the literature the amount of fluid administered greatly facilitated the beneficial influence of extracts. I have repeatedly observed spectacular recovery from coma and from less severe manifestations in adrenalectomized animals and in acute crises of Addison's disease, following the administration of relatively small volumes of physiologic liquids. It does not require much fluid to produce improvement in a cat that is in a severe state of adrenal insufficiency. Thus, in cat 8 the subcutaneous injection of 5 cc. of physiologic solution of sodium chloride at a time when symptoms of adrenal insufficiency were marked caused fully as great improvement as the previous day's injection of a similar amount of adrenal extract corresponding to 150 Gm. of cortex when the symptoms were not yet so severe. It must be remembered that spontaneous improvement may have occurred in either or both instances. In another animal (cat 12) severe symptoms developed in the beginning of the fourth day after excision of the second adrenal. The animal recovered from deep coma after intravenous injection of 20 cc. of physiologic solution of sodium chloride. The next morning a subcutaneous injection of 5 cc. of saline solution at 10 o'clock was followed by greater improvement, and at noon the cat ate some liver, although no food had been taken for two days previously. The animal remained in fairly good condition and was given another subcutaneous injection of 5 cc. of saline solution later in the day. The following day the animal declined, coma developed, and another subcutaneous injection of 5 cc. of saline solution was without effect, death occurring shortly after noon.

It is conceivable that, when adrenal extracts are made from the whole gland, epinephrine or perhaps other substances from the medulla may contribute either good or bad effects when administered. In a few experiments I have prepared extracts from the medulla of glands after dissecting it away from the cortex, using the same process in preparations from both portions of the gland. Such extracts had no demonstrable influence on the survival of adrenalectomized animals but seemed to be capable of reviving animals in acute crisis. They manifested greater toxic action than any extracts of cortex prepared by us and on subcutaneous injection caused severe local irritation, sometimes resulting in sloughing at the site of injection.

CONCLUSION

Not much has been added to knowledge of the adrenal cortical hormone since our demonstration of its availability in extracts of the gland. Obviously, it is not yet possible to rely with safety on the manufacture of such extracts on a commercial scale, for general use. Thus far the evidence offered to support claims of extraction of a purified crystalline hormone has not been convincing, although it may be hoped that this biochemical contribution will be accomplished before long.

Clinical Notes, Suggestions and New Instruments

VALUE OF MUSCULAR EXERCISE IN THE TREATMENT OF DIABETES MELLITUS

SAMUEL SOSKIN, M.D., PH.D.; SOLOMON STROUSE, M.D.; C. O. MOLLANDER, M.D.; BEN VIDGOF, M.D., AND R. I. HENNER, M.D.
CHICAGO

As early as 1868, Trousseau¹ reported the observation that muscular exercise decreased the glycosuria of diabetic patients. Similar observations have been reported by Zimmer² and by Mering and Finkler.³ Külz and Rumpf,⁴ on the other hand, found that while in some diabetic patients the glycosuria decreased after physical exertion, in others it increased. The observations of von Noorden⁵ (by whom the aforementioned references are quoted) agreed with those of Külz. Von Noorden concluded that while in mild diabetes muscular work may decrease the glycosuria, in severe diabetes it has the reverse effect.

With the advent of practical methods for the determination of the blood sugar, Allen⁶ reported that exercise caused a fall in the blood sugar level of diabetic patients. Since the discovery of insulin, Lawrence,⁷ Burger and Kramer,⁸ Gerl

Daily weight and twenty-four hour sugar excretion for the control period and the entire period of physical training. The fasting blood sugar levels are recorded twice a week.

and Hoffman,⁹ and Sendrail and Blancardi¹⁰ have observed that muscular exercise increases the hypoglycemic action of insulin, both in diabetic patients and in normal dogs.

This literature forms the apparent background for the emphasis that modern textbooks¹¹ place on the value of exercise and physical training in the treatment of diabetes mellitus. It will be observed that these references deal with temporary fluctuations in glycosuria and hyperglycemia brought

about by muscular work. We are familiar with only one report that deals with the effects of daily exercise on the diabetic state of an individual observed for weeks. Lawrence¹² reported that an increase in the exercise of such a patient on a constant diet allows the reduction of insulin dosage without increase in diabetic manifestations. Our previous work¹³ has indicated the difficulty of drawing valid conclusions from therapeutic experiments on diabetic patients, unless those patients are under constant and adequate control approaching that of the laboratory. Because of this and because of our distrust of temporary fluctuations in the glycosuria and hyperglycemia as criteria of diabetic tolerance, we undertook the following therapeutic experiment.

METHOD

Two young men, suffering from uncomplicated diabetes mellitus, were admitted to the Max Pam Metabolism Unit of

The preliminary periods in this case illustrate the progressive improvement in diabetic tolerance, so often observed during the initial stages of hospitalization.¹⁴ The period designated "control" is that at which we judged that this initial improvement had reached its limit. It may be seen that the subsequent periods of increasing exercise, encompassing three months of physical training, show no significant decrease in the daily glycosuria or the fasting blood sugar. Repeated tests of the blood sugar level just before and immediately after a period of vigorous exercise in this patient revealed no effect whatever. Thus, during one test it was 147 mg per hundred cubic centimeters before and 148 after, in another it was 166 before and 165 after.

CASE 2—C W, a youth, aged 20, had had diabetes for four years. The physical examination and history were negative except for the diabetes. The basal metabolic rate was 83 plus

‡ The number of minutes recorded in this column indicate the time required for the pulse rate and blood pressure to return to the resting value following the prescribed standard amount of exercise.

the Michael Reese Hospital, where they remained for the entire period of the experiment. Both patients had been unemployed for over a year at the time of admission, and both were in a comparatively poor state of physical training. During a control period of several weeks, in which the patients underwent no more physical exertion than the average ambulatory hospital patient, their diabetic tolerance was established. At the same time their muscular ability and physical condition were measured by suitable tests. Once the control period was over, physical training was begun. Starting with simple setting up exercises, the daily muscular work was gradually increased so as to include walking, rowing, boxing, handball and basketball. The effects of this training on the physical condition and the diabetic tolerance were observed.

RESULTS

Most of the significant data are summarized in table 1. To conserve space, some of the many stages in the experiments have been omitted. The periods detailed in the table therefore present a foreshortened view of the experiments. The figures in each representative period are averages for the number of days specified. The chart graphically presents the daily variations in weight, glycosuria and fasting blood sugar throughout the whole experiment. It should be noted that the blood sugar determinations are fasting values and represent the highest levels attained during the twenty-four hours in these insulin treated cases.

CASE 1—L W, a man, aged 32, had had diabetes for three years. The physical examination and history were negative except for the diabetes. The basal metabolic rate was 44 plus

Here again there was no significant change from the diabetic status of the control period during the course of physical training. The observations as to the immediate effect of exercise on the blood sugar level in this patient are given in table 2.

SUMMARY AND CONCLUSIONS

Two carefully controlled cases of uncomplicated diabetes mellitus have been observed over an extended period before, during and after a systematic course of physical training.

TABLE 2—Effect of Exercise on Blood Sugar Level in Case 2

	Blood Sugar, Mg per 100 Cc
1 Morning test, no food or insulin since previous evening	
1/2 hour before exercise	225
Immediately before exercise	200
1/2 hour of setting up exercises, boxing and rowing	
Immediately after exercise	261
1/2 hour after exercise	290
2 Three hours after lunch and noon dose of insulin	
1/2 hour before exercise	71
Immediately before exercise	61
1/2 hour of exercise as above	
Immediately after exercise	61
1/2 hour after exercise	74

Although the muscular work and the physical conditioning produced their usual salutary effects on the general well being and the muscular power of the subjects, no evidence of a significant improvement in the diabetic tolerance or a decrease in the insulin requirements was obtained.

Special Article

ALTHOUGH A NUMBER OF BACTERIOPHAGE AND ANTIVIRUS PRODUCTS HAVE APPEARED ON THE MARKET DURING THE PAST SIX YEARS, RELATIVELY FEW HAVE BEEN SUBMITTED TO THE COUNCIL ON PHARMACY AND CHEMISTRY. NONE HAVE BEEN ACCEPTED FOR INCLUSION IN NEW AND NONOFFICIAL REMEDIES. INQUIRIES FROM PHYSICIANS, HOWEVER, AND THE ADVERTISEMENTS OF MANUFACTURERS INDICATE THAT THE EXPLOITATION OF THESE PREPARATIONS IS SUFFICIENT TO WARRANT THE PUBLICATION OF A REPORT ON THEM. AS THE SUBJECT IS RELATIVELY NEW AND OBSCURE, AND AS THE PUBLISHED ACCOUNTS OF BACTERIOPHAGE THERAPY ARE CONFLICTING, IT IS OBVIOUS THAT A REPORT LIMITED TO COMMENTS ON THE COMMERCIAL PREPARATIONS WOULD HAVE ONLY A RESTRICTED USEFULNESS. BELIEVING THAT PHYSICIANS DESIRE A MORE EXTENSIVE PRESENTATION OF INFORMATION ABOUT BACTERIOPHAGE AND THE PRINCIPLES AND POSSIBILITIES OF BACTERIOPHAGE THERAPY, THE COUNCIL ON PHARMACY AND CHEMISTRY HAS AUTHORIZED THE PUBLICATION OF THIS REVIEW. IN ADOPTING THIS REPORT THE COUNCIL EXPRESSED APPRECIATION OF THE EXCELLENT WORK OF DRs. EATON AND BAYNE-JONES.

PAUL NICHOLAS LEECH, Secretary.

BACTERIOPHAGE THERAPY

REVIEW OF THE PRINCIPLES AND RESULTS OF
THE USE OF BACTERIOPHAGE IN THE
TREATMENT OF INFECTIONS

MONROE D. EATON, M.D.

AND

STANHOPE BAYNE-JONES, M.D.

NEW HAVEN, CONN.

The purpose of this report is (a) to present summaries and discussions of (1) the experimentally determined facts relating to the bacteriophage phenomenon, (2) the laboratory and clinical evidence for and against the therapeutic usefulness of bacteriophage and (3) the relation of so-called antiviral to materials containing bacteriophage, and (b) to serve as a basis for a survey of the status of some of the commercial preparations. As it is impossible to include in this article an abstract of the whole voluminous and contradictory literature on these subjects, we have summarized only the papers and reviews that have appeared to us to be the most significant.

MODE OF ACTION AND NATURE OF BACTERIOPHAGE

Transmissible lysis of bacteria was discovered independently by Twort¹ in 1915 and by d'Herelle² in 1917. As d'Herelle has stated that he noticed the effect of the lytic agent first in 1909 and as the phenomena described by these two observers differ in some characteristics, there has been a sharp controversy over claims for priority. In recognition of this some authors refer to the process as the "Twort-d'Herelle phenomenon." d'Herelle's observations, however, have had such a widespread influence on the experimental and clinical studies of others that most authors call the phenomenon "bacteriophagy," adopting the name "bacteriophage," which d'Herelle gave to the lytic agent in order to express his belief that it is a living "devourer of bacteria."

The readily demonstrable effects on bacteria in cultures and some of the chief characteristics of the lytic

principle are described briefly in the following modified form of the summary published by Topley and Wilson³ in 1931:

1. Bacteriophage causes partial or complete lysis of bacteria in cultures during the early phases of bacterial growth. In cultures on agar, circular, clear, glassy areas of lysis are produced in the colonies or the edges of the colonies are "moth-eaten" or indented. In broth cultures a partial or complete clearing of the originally turbid fluid occurs as a consequence of the dissolution of the bacterial cells.

2. As a result of the action of bacteriophage on a bacterial culture, variants of the bacterium arise. These variant strains may have increased or decreased virulence as compared with the culture from which they were derived. Many of the variants are completely resistant to the bacteriophage which lysed the sensitive parent culture.

3. Bacteriophage is filtrable through Berkefeld, Chamberland and other bacteria-retaining filters. The lytic principle can be separated by filtration from the intact bacterial cells.

4. Bacteriophage is active (in vitro) in high dilutions. Often one part of lytic filtrate to one billion parts of culture will bring about lysis.

5. Bacteriophage can be propagated in series indefinitely by transference of a small amount of fluid or filtrate from one lysed culture to another young, growing culture of susceptible bacteria.

6. Bacteriophage cannot be propagated on bacteria-free mediums, and the lytic principle does not increase in association with old or dead bacteria, or bacterial products.

7. Young and actively growing cultures are lysed by bacteriophage. Old cultures, cultures not actively growing and cultures in which growth has been inhibited by antiseptics or other means are not dissolved.

8. Bacteriophages are usually specific for species or races of bacteria and have little or no effect on unrelated or dissimilar bacteria. Some lytic principles are strictly specific, others may affect related bacterial species or strains.

9. Changes in the ability of a specimen of bacteriophage to lyse or affect single species or groups of bacteria may be produced by serial propagation in association with susceptible bacteria. The activity of the lytic principle against a specific bacterium may often be increased, and its activity toward other strains may at the same time increase, remain unaffected or decrease.

10. The bacteriophage appears to be a particulate body. So-called races of bacteriophage have been estimated to have diameters of the order of from 10 to 50 millimicrons.

11. Serologic studies indicate that bacteriophages have distinct antigenic properties.

12. The resistance of bacteriophage to heat and chemicals is less than that of bacterial spores but slightly greater than that of vegetative cells. It withstands aging for long periods.

Space does not permit a thorough discussion of the highly controversial question of the nature of bacteriophage. The various views on this subject may be grouped as follows:

THEORIES

1. d'Herelle⁴ has always contended that the bacteriophage is a living submicroscopic virus, parasitic on susceptible bacteria. The principal point of evidence in favor of this view is the fact that the lytic agent may be propagated indefinitely in cultures of susceptible bacteria. d'Herelle regards this as evidence of multiplication. Phenomena of apparent adaptation, antigenic specificity and analogies to filtrable viruses are cited by d'Herelle as additional support for his opinion. These and other arguments advanced by d'Herelle are

plausible and are not refuted by the facts. They have not, however, been accepted generally and are not more convincing than other lines of evidence in favor of other views. It is obvious that the theory of d'Herelle is of great scientific influence and importance. Unfortunately it has been exploited detrimentally by manufacturers of commercial bacteriophage preparations, as has been pointed out in several editorials in *THE JOURNAL* on the "bacteriophage metaphor."⁵

2. Many investigators have regarded the bacteriophage as an inanimate substance, perhaps an enzyme or activator of an endocellular hydrolytic bacterial enzyme, having its origin in the bacterial cell which it lyses and, being capable of lysing other cells, increasing in amount in the process. The absence of convincing evidence of the living nature of bacteriophage and the results of studies on the mode of action of the lytic principle, and the effects of substances on it, have favored this theory. A review of this evidence has been presented by Bronfenbrenner.⁶ More recent evidence in support of it has been provided by Krueger and Tamada,⁷ Krueger and Northrop,⁸ Hetler and Bronfenbrenner⁹ and Krueger and Baldwin.¹⁰

3. Bordet and his associates,¹¹ Arkwright¹² and other investigators have held the opinion that bacteriophage is an inanimate substance which affects physiologic or hereditary processes of the sensitive bacteria in such a way that early death and autolysis of the culture is brought about. This tendency to rapid autolysis may be transmitted from generation to generation by heredity, and autolysis of the cells liberates the substance that may in turn affect other sensitive bacteria.

4. Hadley,¹³ like d'Herelle, has emphasized the ability of the bacteriophage to induce rapid and extensive variation in bacterial cultures, aside from its lytic activity. This fact, coupled with other lines of evidence, has led Hadley to postulate that the bacteriophage is a filtrable stage in a complex life cycle of a bacterium. According to this view, the bacteriophage stimulates the microscopically visible bacteria of the culture to pass into a submicroscopic filtrable stage. This theory resembles the older "splitter" theory of Bail and has some elements in common with discussions of the possible independent viability of genes. The occasional late growth of bacteria in lytic filtrates and observations made with serial transfers have been the basis of the claims made by Hadley¹⁴ and by Kendall

and Walker¹⁵ that this process can be reversed and that living, microscopically visible, bacteria of the original species can be recovered from filtrates of lysed cultures. Adequate confirmation of this work is lacking at present.

ORIGIN OF BACTERIOPHAGE

Closely bound up with the nature of the bacteriophage is the problem of its origin. d'Herelle believes that the principle has a single original source, possibly in the intestines of man and animals (because of the abundance of bacteriophage in sewage) and that all specific lines of the bacteriophage have been derived from this by a process of adaptation to particular bacterial species. On the other hand, Hadley believes that the production of bacteriophage from such sources as sewage and pancreatic extracts is due to the effect of some substance on the bacterial culture which causes the appearance of bacteriophage from the culture itself. Good evidence of the spontaneous origin of bacteriophage in previously unaffected cultures is lacking. Lytic filtrates of sewage are usually mixtures of bacteriophage, which require purification for specific studies.¹⁶

It was pointed out in the beginning of this report that many lines of bacteriophage are highly specific. Thus a bacteriophage may act strongly on one strain of *Bacillus coli* and weakly or not at all on another. A certain degree of adaptation of the lytic principle can take place by serial passage through many cultures of the same strain of bacteria. The importance of these facts in the therapeutic application of the bacteriophage will be pointed out later. Similarly, the inverse adaptation of bacteria to bacteriophage, the production of resistant forms and variants, must be considered.

The bacteriophage filtrate, when injected into an animal, possesses the ability to produce an antibacteriophage. The serum of the immunized animal will sometimes inactivate the homologous bacteriophage or inhibit its activity. Repeated injection of bacteriophage is followed by increasing rapid disappearance of the lytic agent from the blood.¹⁷ The nature and extent of this effect is not at present fully understood.

COMPOSITION OF LYTIC FILTRATES

In any discussion of the therapeutic effects of the bacteriophage, the composition of the filtrates of lysed cultures must be borne in mind. Practically all bacteriophage preparations are made by filtering broth cultures of bacteria which have been lysed by the bacteriophage. These filtrates, although generally called "bacteriophage," contain in addition to the lytic principle a number of other substances, which may be divided into two classes:

1. Those substances originally present in the sterile broth used to grow the bacteria. These include meat extractives and muscle proteins; amino-acids, peptones and proteoses; nitrogenous organic bases, and a number of other substances, many of which are of unknown composition.

2. Those substances derived from the bacteria themselves. These include antigenic substances derived from the bacteria such as the bacterial proteins, prod-

ucts of the metabolism of the bacteria, and other substances resulting from the lysis of the bacteria. In this class may also be included the so-called antiviral of Besredka.¹⁸ Besredka reports that the antiviral is present in filtrates of broth cultures of various organisms. Lysis by the bacteriophage is not necessary to liberate it.

It is difficult or impossible to separate the bacteriophage from many of these substances; consequently the reported effect of lytic filtrates when injected into an animal or man may be due, in part at least, to substances other than the bacteriophage. Among the most important of these effects to be considered are:

1. Protein shock as a result of the proteoses, peptones and bacterial proteins.
2. Immunization by the antigenic bacterial proteins. This would require a period of at least four or five days before an effect would be noticeable.
3. The antiviral effect reported by Besredka.

REVIEW OF BACTERIOPHAGE THERAPY

Since the majority of the claims for the therapeutic use of bacteriophage have been based on its ability to lyse bacteria, and apparently destroy them, it seems advisable, before the literature on the clinical use of the bacteriophage is reviewed, to cite a number of experiments which may help to answer the question Does bacteriophage lyse susceptible bacteria in vivo as it does in vitro?

1. *In Vitro Experiments Relating to Bacteriophage Therapy.*—d'Herelle claimed that the lytic process produced by the bacteriophage is not modified by normal serum, ascitic fluid, or urine, although he admits that bile is inhibitory. These conclusions have been tested by a large number of experiments both in vitro and in vivo and have been contradicted in many cases. Thus whole blood from human beings or animals has been shown to be markedly or completely inhibitory to the lysis of streptococcus, staphylococcus, typhoid bacillus, and colon bacillus by the homologous bacteriophage (Friedberger and Vallen,¹⁹ Clark and Clark,²⁰ Appelbaum and MacNeal,²¹ Evans²²). The inhibitory action of blood appears to be due mainly to the serum portion as reported by Evans²² and by Appelbaum and MacNeal.^{21a} A large number of other investigators have also noted the inhibitory action of human or animal serum on bacteriophage for staphylococcus, streptococcus, colon bacillus, anthrax bacillus, dysentery bacillus and subtilis bacillus, the inhibition being almost complete with undiluted serum (Gratia and Jaumain,²³ Zdansky,²⁴ Riding,²⁵ Cowles and Hale,²⁶ Gratia and

Mutsaers,²⁷ Colvin²⁸). When the serum is diluted the degree of inhibition becomes less and varies with the source of the serum and species or strain of bacterium and bacteriophage under investigation. Since the experiments cited have been adequately confirmed and are at present practically undisputed, there is convincing evidence that the action of bacteriophage is markedly inhibited by whole blood and undiluted serum.

Results of studies on the effect of other body fluids on the bacteriophage have been more variable. Colvin²⁸ and Evans²² have noted the inhibitory effect of pus on bacteriophage for streptococcus and anthrax bacillus. Bruynoghe and Maisin²⁹ noted the disappearance of bacteriophage activity in the pus of staphylococcal abscesses. Appelbaum and MacNeal^{21a} found that purulent exudate was inhibitory in concentrations as high as 1:1,000 for staphylococcus bacteriophage. However, the same authors found that pus in similar experiments had very little inhibitory action on colon bacillus bacteriophage.

The inhibitory action of urine seems to be less striking in most cases than is that of other body fluids (Colvin²⁸ and Evans²²). Colvin found that the lysis of staphylococcus by the homologous bacteriophage in the presence of urine was complete in the case of one strain, partial with another strain and negative with a third strain. Larkum³⁰ made similar observations.

TABLE 1—Inhibitory Action of Body Fluids

Marked or Complete Inhibition with All Bacteriophages So Far Investigated	Degree of Inhibition Varies with Different Bacteriophages and Different Animal Species
	Pus Urine Ascitic fluid Cerebrospinal fluid
Whole blood	
Undiluted serum	
Bile	
Saliva (streptococcus only)	
Autoclaved intestinal mucus (dysentery only)	

The inhibitory action of bile seems to be undisputed.

Several of the authors already cited have investigated the action of other body fluids on bacteriophage, including ascitic fluid, saliva, cerebrospinal fluid and autoclaved intestinal mucus. The results of the work on the inhibitory action of these and the other body fluids already mentioned are summarized in table 1.

Further confirmatory evidence of the inhibitory action of body fluids is offered by the experiments of Dresel and Lewis,³¹ with tissue cultures infected with mouse typhoid bacilli and subjected to the homologous bacteriophage. With mouse tissue and chicken tissue in plasma and Ringer's solution the bacteriophage failed to lyse the susceptible organisms but remained in the cultures for as long as eleven days. When the cultures were spread on agar, lysis of the organism proceeded. The bacteriophage did not appear to affect the growth of the tissue cells, nor did the cells destroy the bacteriophage. The lytic agent remained in a state of suspended activity in the tissue cultures.

2. *Bacteriophage Therapy in Experimental Animals.*—Bronfenbrenner⁶ has pointed out that one of the chief points of evidence against the therapeutic value of

the bacteriophage is the almost uniform failure of a large number of investigators to demonstrate a curative effect of the lytic principle in carefully controlled laboratory experiments on infected animals. In a more recent review, Hoder³² cites a similar series of experiments, most of which were negative.

Attempts to treat staphylococcus and streptococcus septicemias in rabbits and mice have without exception failed, even when the bacteriophage is injected simultaneously with the bacterial culture. (Clark and Clark,³⁰ Eliava,³³ Krueger, Lich and Schulze,³⁴ Evans²²). Failure to affect the course of Shiga dysentery and *Bacillus coli* infections by simultaneous injections of bacteriophage in rabbits was also reported by Eliava. Harris and Larimore³⁵ reported no protective or curative effect of bacteriophage in typhoid infections in guinea-pigs and mice. On the other hand, a few positive results have been reported when active bacteriophage was injected simultaneously with organisms of the colon-typhoid-dysentery group into rabbits and mice, but injection of the . . . thirty minutes to three days later . . . the course of the infection (Arnold and Weiss³⁶ and Walker³⁷).

Many attempts to treat experimental plague in various laboratory animals have been unsuccessful. In rabbits, guinea-pigs, white rats, and mice the injection of bacteriophage failed to influence the course of the disease (Compton,³⁸ Flu³⁹ and Naidu and Avari⁴⁰). Flu also performed a series of experiments on chickens, which are not susceptible to plague but carry the bacillus many days in the blood. He was unable to demonstrate that the injection of bacteriophage caused any decrease in the number of bacilli in the circulating blood. In a similar experiment, using rabbits with Shiga bacillus bacteremia, Kabéshima⁴¹ was unable to demonstrate a sterilization of the blood in seven days by the repeated intravenous injection of Shiga bacteriophage, but the length of time required raises the question as to whether active immunity was produced and not actual lysis of the organism.

The treatment of experimental infections of a more or less localized character has been studied to a limited extent. *B. coli* cystitis in rabbits and guinea-pigs is reported by Larkum⁴⁰ and Marcuse⁴² to be cured or markedly alleviated by the action of the bacteriophage. In a study of the effect of bacteriophage on staphylococcal and streptococcal skin lesions in rabbits, Walker⁴³

found that, although admixture of the lytic principle and the organisms immediately before injection caused a reduction in the size of the lesions, no effect on the lesions was produced by local or intravenous injection either immediately after injecting the organisms or after the lesions had developed. Kolmer and Rule⁴⁴ succeeded in reducing the mortality of experimental streptococcal meningitis in rabbits from 100 per cent to about 60 per cent by injection of bacteriophage into the carotid artery.

The early experiments of d'Herelle on fowl typhoid, in which the mortality was reduced from 95 per cent or over to 5 per cent by treatment with bacteriophage, held out great promise for the use of this agent in therapeutics. On the basis of these experiments d'Herelle has contended that bacteriophage therapy is applicable only to natural infectious diseases and that experiments on artificially infected animals were not valid. In hemorrhagic septicemia of water buffaloes, on the contrary, d'Herelle could demonstrate no therapeutic effect of the bacteriophage although an immunity was produced twenty days after the injection of the lytic filtrate. Colvin,⁴⁵ using a bacteriophage of maximum activity in vitro, had little or no success in the treatment of infectious streptococcal lymphadenitis of guinea-pigs. There was some evidence that bacteriophage therapy was not entirely harmless. In an extensive series of experiments on the effect of bacteriophage on epidemic mouse typhoid caused by *Bacillus aertrycke*, Topley, Wilson and Lewis⁴⁶ concluded that there was no reduction of the mortality or the excretion of the organisms even though the bacteriophage was fed to the infected mice over a period of three months. Colvin⁴⁵ has pointed out that at least five other investigators have failed in attempts to treat mouse typhoid with bacteriophage. Pyle⁴⁷ reported similar failures in the treatment of pullorum disease of chickens with a bacteriophage that was highly active for the infecting organism in vitro.

From a consideration of the laboratory experiments just described, it is evident that the bacteriophage does not produce any such dramatic effect on susceptible bacteria in the animal body as it does in the test tube. In many of the experiments cited, the conditions appeared to be ideal for the lysis of the organisms by the bacteriophage, but in practically all cases no effect was produced, probably because of the inhibitory action of the body fluids and tissues on the lytic principle. Judging from the experiments cited, the greatest chance for success in the therapeutic use of the bacteriophage would be in localized infections of certain of the body cavities where these inhibitory conditions are at a minimum, as in the bladder, in the subarachnoid space, perhaps in the intestine, and possibly in abscess cavities and wounds. Of the various species of bacteria studied in experimental infection, some members of the colon-typhoid-dysentery group seem to be slightly more susceptible to the action of the bacteriophage in vivo than do the pyogenic cocci and other bacteria. But even with the most susceptible organisms under the least

inhibitory in vivo conditions, no extensive lysis or destruction of bacteria by bacteriophage has been demonstrated.

3. Bacteriophage Therapy in Human Infections.—

The many reports of good results from the use of bacteriophage in human infections make it difficult to assert that lytic filtrates of bacterial cultures are without effect in the treatment of suitable cases. However, most of the work reported has been done without adequate controls, and consequently the results obtained are difficult to evaluate. It has been the general experience in medical research that therapeutic agents which are effective in human disease have previously been found effective in suitably conducted laboratory experiments on animals. This is not the case with the bacteriophage. In the previous section it has been pointed out that controlled therapeutic experiments with the bacteriophage in both artificially induced and spontaneous infections in animals have generally failed; and as will be seen in the following review, in the few instances in which various investigators have used adequate controls during the treatment of human diseases with bacteriophage the results have usually indicated no therapeutic effect.

In the many clinical trials of the bacteriophage in various infections, most of the results have been judged on a previous conception or knowledge of the clinical course of the disease, and many of the diseases treated were self limiting and nonfatal. This may to a large extent account for the conflicting views as to the therapeutic value of the bacteriophage. d'Herelle⁴⁸ has explained most of the failures in bacteriophage therapy as being due to the use of bacteriophage which was not active or "virulent" enough to destroy the infecting organism. For this reason in vitro lysis of the infecting organism by the bacteriophage should always be demonstrated, preferably before the agent is used in treatment.

Many of the conflicting results reported may also be due to differences in the mode or frequency of administration. Bacteriophage has been administered intracutaneously, subcutaneously, intravenously, by mouth, by rectum and by local applications such as wet dressings or irrigations, depending on the nature and location of the infection. For example, in enteric diseases one investigator may use the oral route, another subcutaneous injection, and a third intravenous injection. In some cases large amounts of bacteriophage, up to 100 cc., are administered at frequent intervals, in others only 1 or 2 cc. is injected every twenty-four to forty-eight hours.

The question of the fate of the bacteriophage after injection into the animal body is answered in part by experiments of Appelmans⁴⁹ and of Nungester and Watrous.⁵⁰ Appelmans observed that bacteriophage is not absorbed from the digestive tracts of normal animals. When injected, it is rapidly eliminated in the urine and feces. Only traces can be detected in the heart, liver, lungs, testicles and blood after twenty-four hours. The bacteriophage appears to accumulate in considerable quantities in the spleen and can be detected there five days after injection. Nungester and Watrous have confirmed these observations and noted a large accumulation of bacteriophage in the spleen two hours after injection. These experiments do not take into consideration the effects of the presence of susceptible

infecting organisms, which may act as carriers of the bacteriophage and affect its distribution. Inflammatory processes also appear to affect the distribution of bacteriophage, as shown by the experiments of Eliava⁵¹ and Sumiyoshi.⁵² The latter investigator fed bacteriophage to guinea-pigs and then induced a peritoneal inflammation by injection of bacteria. The demonstration of the lytic principle in the exudate indicated that it had passed from the intestine to the peritoneum. Eliava cites an experiment in which bacteriophage injected into the blood stream was detected after three hours in the peritoneal exudate produced by injection of sterile broth. Control guinea-pigs were negative for bacteriophage.

The therapeutic effects reported may or may not have been due to bacteriophage itself. Owing to the complexity of the lytic filtrates employed, the effects in one disease may have been due to the action of entirely different factors from those in another disease. Both in animal and in human experiments very few attempts have been made to control the results by the use of nutrient broth alone, the use of culture filtrates without bacteriophage, or the use of lytic filtrates in which the bacteriophage has been destroyed. Furthermore, as already reported, the action of the bacteriophage on bacteria is by no means limited to lysis of the organisms. These questions will be discussed in greater detail in connection with the review of the literature on bacteriophage therapy.

Bacteriophage in Staphylococcic and Streptococcic Infections.—A great many of the reported favorable results of bacteriophage therapy have come from the use of this agent in staphylococcic infections. The difficulty in obtaining active polyvalent bacteriophage for many of the streptococcus strains has precluded its use to some extent in infections with this organism. The infections treated have been local and the generalized infections, bacteremia and septicemia.

Since it is well known that septicemias caused by the pyogenic cocci have a mortality of from 40 to 50 per cent, these cases would seem to present suitable clinical material for testing the therapeutic value of the bacteriophage. The severity of these cases, however, varies between that of a mild bacteremia and that of a severe septicemia. It must be remembered also that in these cases the blood undoubtedly inhibits the lysis of the bacteria, that a concentration of bacteriophage in the blood great enough to produce lysis is probably seldom if ever reached,⁵³ and that the absence or slowness of multiplication of the bacteria in the blood stream makes regeneration of the bacteriophage negligible.

Despite these facts, results considered by the authors to be favorable have been reported for the use of bacteriophage in blood stream infections with staphylococcus and streptococcus. Brulé and Sauvé⁵² have reported the cure of a case of staphylococcic septicemia following one injection of bacteriophage and a blood transfusion. Schultz⁵³ reports that ten cases of septicemia were treated by intravenous injection of bacteriophage "with remarkable results in several cases." These reports are too limited to be convincing. MacNeal and Frisbee⁵⁴ have reported a series of fifteen

cases of staphylococcic bacteremia treated by intravenous injection at frequent intervals of an asparagine preparation of bacteriophage which was low in protein content to avoid serious reaction. More recently MacNeal, Frisbee and Applebaum⁵⁵ have reported the occurrence of at least one serious reaction from the use of asparagine bacteriophage preparations by intravenous injection in *B. coli* septicemia. Several of these cases were also treated by transfusion and by local application of bacteriophage at the site of infection. Of the fifteen patients treated, eight died. MacNeal and Frisbee⁵⁴ report that previous to 1929 all patients with staphylococcic bacteremia seen by them who gave two successive positive blood cultures invariably died. They believe that the action of the bacteriophage is not due to lysis but to sensitization of the bacteria, so that they are more susceptible to the immune action of the body fluids and to phagocytosis. Dutton⁵⁶ reports that he has treated twelve cases of staphylococcic bacteremia with eleven recoveries and only one death. Of these twelve cases, five might not have been, in the opinion of Dutton, true septicemias. Rice⁵⁷ reports that two patients with staphylococcic septicemia treated by subcutaneous injection of bacteriophage died. Stout⁵⁸ reports two cases of staphylococcic septicemia, in one of which the patient was not treated by bacteriophage and recovered, and one treated also recovered. Dutton⁵⁶ has reported the results of the treatment of streptococcic septicemia. Of fifteen patients not treated by bacteriophage seven died, and of forty patients treated by bacteriophage only eleven died. This represents a reduction in mortality from approximately 46 to 28 per cent.

The series of cases cited are probably not large enough to have statistical significance, but all the authors believe that the bacteriophage is of value in the treatment of septicemia. However, the results are not entirely convincing, since it is known that the mortality in these conditions is probably not over 40 to 50 per cent and in the most detailed report, that of MacNeal and Frisbee,⁵⁴ the mortality of the treated cases is just over 50 per cent.

The cure of one case of staphylococcic meningitis is reported by Schless.⁵⁹ After an intensive review of the literature this author concludes that true staphylococcic meningitis is invariably fatal. In the case reported the purulent spinal fluid showed a pure culture of *Staphylococcus aureus* on three successive days, the blood culture remaining negative. Intraspinal administration of bacteriophage (from 10 to 40 cc.) was followed in twenty-four hours by negative spinal fluid cultures, disappearance of toxic symptoms and loss of rigidity. The results indicate that actual lysis of the organisms in the subarachnoid space might have occurred. Since the blood cultures were always negative it seems evident that the infection was limited to the meninges. Stout⁵⁸ also reports treating two patients suffering from staphylococcic meningitis with bacteriophage. Both patients recovered, but this author gives no details.

In the bacteriophage treatment of local staphylococcic infections the results are difficult to evaluate because of the tendency of such lesions to heal spontaneously. In the pyodermias, such as furunculosis, carbuncle and acne, favorable results have been reported in a large series of cases by a number of investigators. Gratia⁶⁰ was among the first to recommend bacteriophage for the treatment of staphylococcic infections. Therapeutic observations on experimental animals and in human cases by this author indicated that the lytic agent accelerated the cure of these conditions. Bruynoghe and Maisin,⁶¹ and Gougerot and Peyre⁶² also reported favorable results in furunculosis, acne and sycosis. In the treatment the bacteriophage was injected into and around the lesions and also applied in the form of wet dressings to the lesions, which had been previously opened. In these early cases all the authors reported that a marked local reaction followed the application of the bacteriophage and that this was followed by a liquefaction of the pus and regression of the infection in from twenty-four to forty-eight hours. Grenet and Isaac-Georges⁶³ reported that thirty-eight of forty cases of furunculosis responded favorably to bacteriophage therapy, with only two or three recurrences.

In the more recent literature of bacteriophage therapy of pyodermias in America a great many favorable results have been recorded. Schultz,⁶⁴ in summarizing the results of treatment by physicians in California, gives the following statistics:

Of sixty-three cases of furunculosis, forty-four "helped" by bacteriophage

Of sixteen cases of carbuncle, fourteen healed rapidly by bacteriophage.

Of twenty-nine cases of acne, fifteen recovered after application of bacteriophage.

In this series only effects that appeared from twenty-four to seventy-two hours after the administration of the bacteriophage were considered. Crutchfield and Stout⁶⁴ report that the clinical results of treatment of fifty-seven patients with staphylococcic skin infection were much better than in similar cases in which other means of treatment were used. In a later report Stout⁵⁸ gives the following summary of cases treated by bacteriophage:

The treatment of boils was successful in 85 per cent.

The treatment of generalized furunculosis was successful in 75 per cent.

The treatment of chronic recurrent furunculosis was successful in 60 per cent.

The treatment of carbuncles gave inconsistent results

In impetigo neonatorum, twenty-four cases were cured in from twenty-four to forty-eight hours with treatment

In impetigo, sixty cases showed good results from early treatment.

Acne and sycosis were rarely affected by bacteriophage therapy.

Although the number of cases of each disease is not mentioned, Stout states that the whole series included about 1,500 cases. Boyce, Lampert and McFetridge⁶⁵

report the treatment of thirteen cases of furunculosis and twenty-seven cases of carbuncle, and Alderson⁶⁶ reports the treatment of ten cases of acne vulgaris and furunculosis by bacteriophage with good results. Kahn⁶⁷ found that in nine cases of acne and five cases of furunculosis the use of stock polyvalent bacteriophage produced a "50 to 90 per cent" improvement and was effective even in cases in which every other treatment had failed. He notes prompt healing of the lesions, the abortion of some boils, and the liquefaction of pus in others. Cipollaro and Sheplar⁶⁸ review a series of 108 cases of pyodermias treated by them. Of these cases, sixty-two were furunculosis in all but fourteen of which treatment was completed with cure. They believe that the effects in recurrent multiple furunculosis may be due to an immunity conferred by the bacteriophage. They consider surgery the method of choice in solitary boils in which the pus is encapsulated. In five cases of carbuncle Cipollaro and Sheplar obtained good results, noting that the pus is liquefied, toxemia and pain reduced, and recovery more prompt than when incision and drainage are used. They report fair results in the treatment of twenty-eight cases of sycosis vulgaris, only seven of their patients having failed to show any improvement. These authors also note local and general reactions from the injection of bacteriophage, usually followed by marked improvement in the condition of the patient.

Larkum⁶⁹ has presented the data collected by the Michigan Department of Health on the treatment of 208 cases of furunculosis by bacteriophage. In these cases the same polyvalent strain of bacteriophage was used throughout. The preparation contained the equivalent of five billion staphylococci per cubic centimeter. Treatment consisted of injection of 2 cc. subcutaneously on two successive days. Local applications were not used in furunculosis. The author summarizes the results first in groups according to the previous duration of the disease. This summary indicates that the previous duration makes no difference in the results. The general summary is given in table 2.

Larkum states that in thirteen instances patients cured by bacteriophage had previously failed to respond to autogenous vaccines. Of twenty-three cases of acne treated by bacteriophage, two were cured, eight improved and thirteen failed to respond. Rice⁵⁷ has also treated a large series of cases of staphylococcal infections. Stock bacteriophages were used for all except the first fifty cases. Cultures from cases which failed to respond were generally found to be resistant organisms. Several cases were treated with peptone broth, with some improvement but no striking effects. Sixty-six cases of boils and carbuncles were treated, with "excellent results" in fifty-five, intermediate results in five, failure in five, and no report in one. Four of the failures could be ascribed to the fact that the causative organism was not susceptible to the bacteriophage used. Wet dressings were used in a great number of cases, and subcutaneous injection was used in some. Thirty-five cases of acne were treated, with thirteen "excellent results," eight "fair" results, seven

with no effect, and treatment was incomplete in seven. In these cases the bacteriophage was applied in 1 per cent agar jelly. Both Rice and Larkum are inclined to the view that factors other than the lysis of the bacteria may play a part in the healing of the lesions. Larkum believes that many of the cures may be due to immunization with a readily available antigen. Rice, on the other hand, reports almost equally good results in cases that have been treated by wet dressings, or local instillation into the lesion, without the use of filtrates as a vaccine. In cases in which striking effects were reported to have occurred between twenty-four and forty-eight hours it is difficult to account for the improvement as being the result of active immunity.

In the treatment of osteomyelitis by bacteriophage, the reports have been generally less enthusiastic than those in the treatment of pyodermias. In osteomyelitis, streptococcus as well as staphylococcus may play an important rôle. Since no potent polyvalent bacteriophages are available for streptococci, attempts to treat streptococcal bone infections with bacteriophage might be expected to meet with little success. In most of the cases reported the ordinary methods of surgical inter-

TABLE 2—General Summary in Larkum's Series

Patients treated	208
No recurrences 6 months after treatment	88
No recurrences from 6 weeks to 6 months after treatment	61
No recurrences less than 6 weeks after treatment	13
Total number of patients showing no recurrences immediately to more than 6 months after treatment	162 (78 per cent)
Recurrences	46 (19 per cent)
Mild recurrences which later cleared up	30
Improved but occasional recurrences	10
No improvement	6 (3 per cent)
Reactions observed as follows:	
None	60
Mild	73
General	15
Severe	2
No report	56

vention have been used along with the bacteriophage therapy. Bagley and Keller⁷⁰ report treating ten cases of osteomyelitis with bacteriophage. Three cases in which infecting organisms other than staphylococcus were present were treated only with bacteriophage dressing. None of these cases showed improvement. Three cases, complicated by septicemia, were treated by dressings and by intravenous injection of bacteriophage. Severe reactions followed the intravenous injections in all these cases. Two of the patients died, one recovered. Four cases of uncomplicated staphylococcal osteomyelitis were treated by bacteriophage, wet dressings and subcutaneous and intramuscular injections being used. Three showed good results; one patient died of meningitis extending from osteomyelitis of the skull. The authors mentioned that uncomplicated cases of osteomyelitis respond best to other forms of treatment. Boyce, Lampert and McFetridge⁶⁵ report that the bacteriophage treatment of ten cases of osteomyelitis produced some relief but no striking effects. Rice⁵⁷ states that in eleven cases of osteomyelitis bacteriophage therapy gave excellent results in four, fair results in three, and no effect in four. He is of the opinion that the value of bacteriophage is less in this condition than is indicated by these figures. It has no value when

dead bone is present in the lesion. MacNeal⁷¹ and Larkum⁶⁸ report favorable results in the treatment of a small series of cases. Albee⁷² states that in about 94 per cent of cases of acute and chronic osteomyelitis observed by him a specific bacteriophage occurs spontaneously. He believes that the efficacy of the Orr closed treatment for osteomyelitis, in which the wound is closed without antiseptics and the dressings remain long undisturbed, is due to the spontaneous development of bacteriophage. This is merely a reiteration of d'Herelle's theory⁷³ of the rôle of bacteriophage in immunity to infectious disease, a theory that at present lacks experimental support.

(To be continued)

Council on Physical Therapy

THE FOLLOWING REPORT WAS SUBMITTED TO THE BOARD OF TRUSTEES OF THE AMERICAN MEDICAL ASSOCIATION AT A JOINT MEETING OF THE TRUSTEES AND THE COUNCIL, HELD IN CHICAGO, SEPT. 17, 1934. THE TRUSTEES EXPRESSED THE VIEW THAT THIS REPORT MIGHT WELL BE PUBLISHED FOR THE BENEFIT OF THE ENTIRE PROFESSION, IN ORDER THAT THE PHYSICIANS OF THE COUNTRY MIGHT BETTER UNDERSTAND THE PURPOSE OF THE COUNCIL, ITS AIMS, ACCOMPLISHMENTS AND PLANS FOR THE FUTURE.

H. A. CARTER, Secretary.

REPORT OF THE COUNCIL ON PHYSICAL THERAPY

The Council came into existence as the result of a resolution adopted by the House of Delegates in 1925. The members of the Council were appointed by the Trustees during the fall of 1925. The Council held its first meeting in January 1926. The Council has been actively in existence for eight years.

Physical therapy was in a chaotic condition at the time of the organization of the Council by the Trustees. During the war physical therapy had been elevated from the realm of quackery, but by 1926 it bid fair to lead many of our profession back into the realm of quackery. It was recognized as having many excellent attributes of therapeutic value by the majority of the profession, while at the same time it was frowned on by many of the conservative men of the profession as being tainted with quackery.

At this time only a few hospitals had adequate physical therapy departments, and only a few physicians were employing it solely for the welfare of their patients. The chaos that existed was due to the activities of manufacturing agents who were selling apparatus directly to the physicians and to hospitals for "machine therapy." A few manufacturers were sending physicians of questionable repute throughout the country to hold clinics for the purpose of demonstrating machines that would deliver certain forms of physical therapy, for which all kinds of unwarranted and unsupported therapeutic claims were made. The profession was rapidly losing sight of the fact that true physical therapy consisted chiefly of intelligent hand work—namely, heat, massage and exercise—and that expensive machines and apparatus played a minor part in the realm of physical therapy so far as the majority of the profession was concerned.

With the foregoing conditions confronting the newly formed council, it can be readily understood that the first two or three years of the Council's existence were devoted to self education of its members; to formulating rules of procedure that could withstand all criticism; and to months—even years—of study of certain physical phenomena used in physical therapy before it could refute or approve the therapeutic claims made by certain manufacturers. This was a new field in therapeutics to the Council members as well as to most of the members of the profession, and of necessity they had to move surely and cautiously

if the work of the Council was to be permanent. It is with a sense of real accomplishment that the Council presents the following outline:

I. The Council—its organization and activities relating to physical therapy apparatus.

A. The Council consists of twelve men: one internist, two physiologists, one pathologist, one physicist, one radiologist, one dermatologist, two orthopedic surgeons, one general surgeon, and two physical therapists.

Six of the original members appointed by the Council are still active. Two of the Council members were lost by death and four by resignation; two were not reelected; their places were immediately filled by others appointed by the Trustees.

B. The Council has prepared and adopted:

1. Official Rules and requirements for submission of apparatus.

2. Minimum standards for acceptance of apparatus; e. g.,

(a) Regulations to Govern the Advertising of Ultraviolet Generators to the Public and to the Medical Profession.

(b) Acceptance of Sunlamps.

(c) Diathermy: A Preliminary Statement to the Acceptance of Diathermy Apparatus.

C. The Council has developed a list of definitions and nomenclature by cooperating with the American Standards Association. This is the first complete list of nomenclature for which the definitions of the terms correspond with the similar terms in use by physicists, engineers and other scientists.

D. The Council has secured the services of leading physicists, physiologists, clinicians and others, who have served as consultants and as investigators of apparatus.

E. The Council has made extensive study and investigation of ultraviolet, visible and infra-red radiation and has corrected many of the abuses of radiation therapy due to the lack of familiarity in the profession concerning this form of treatment. The Council has

1. Investigated a great many types of ultraviolet lamps and developed the emission standards for certain grouping of lamps.

2. Has developed and adopted ultraviolet radiation dosage units in general use in the United States.

3. Has developed and adopted standards for the control of ultraviolet radiation advertising to the profession and to the public.

4. Has conducted investigations into x-ray and radium products and therapeutic practices.

F. The Council has cooperated with the American Standards Association, working with the American Society of Ventilating Engineers in the investigation of air conditioning and health claims in connection therewith.

G. The Council has cooperated with the Council on Medical Education of the American Medical Association, the American Orthopedic Association, the American Congress of Physical Therapy and the American Physiotherapy Association, (technicians) and the American Occupational Therapy Association, in developing standards for the education of technicians.

H. The Council has published sixty-two articles, which have dealt chiefly with those physical therapy procedures most applicable to the work of the general physician; which have refuted many false therapeutic claims for certain physical therapy apparatus, and which have otherwise endeavored to place physical therapy on a sound basis. Many

71. MacNeal, W. J.: Bacteriophages as Help in Treatment of Infections in Children, *New York State J. Med.* 31: 1383-1386 (Nov. 15) 1931.

72. Albee, F. H.: Will Bacteriophage Prove Ideal Wound Treatment? *Am. J. Surg.* 15: 228-236 (Feb.) 1932.

73. d'Herelle, Felix: Immunity in Natural Infectious Disease, Baltimore, Williams & Wilkins Company; translated by G. H. Smith, 1924.

of these articles have been included in the Handbook of Physical Therapy.

I. The Council has edited and published a Handbook of Physical Therapy.

II. Apparatus: The Council

- A. Has formally considered 290 pieces of apparatus.
- B. Has accepted 130 pieces of apparatus.
- C. Has published the rejection of seventeen pieces of apparatus.
- D. Has 143 pieces of apparatus still under consideration. A large portion of these have been investigated and rejected, but at the request of the manufacturers the publication of these reports has been postponed while the firms are gathering better evidence.
- E. Has withdrawn acceptance of one product.
- F. Has refused to consider about 100 mechanical nostrums.
- G. Has investigated, standardized and suggested improvements in anesthesia, resuscitation and oxygen therapy equipment. Under these heads fifteen pieces of apparatus have been accepted.
- H. Has cooperated with the Section on Ophthalmology of the American Medical Association in the investigation of lenses and ophthalmologic devices.
- I. Has investigated certain ear-exercising devices, many pollen-removing appliances, all kinds of mechanical exercisers, belts, pads, electric blankets, and innumerable other devices with questionable health values.

III. Advertising: The Council

- A. Has assisted in raising the tone of advertising matter and has been instrumental in the improvement of merchandising methods.
 1. By reading, revising and in many cases completely eliminating approximately 5,000 separate pieces of advertising material.
 2. By securing the cooperation of the better manufacturers.
 3. From the standpoint of physicians, hundreds of letters have been received showing their favorable reaction to improved advertising and merchandising methods.
- B. Has eliminated "clinics" that were conducted by manufacturers for the demonstration of their apparatus.
- C. Has eliminated almost completely the giving of lectures throughout the country by physicians of questionable repute, employed by manufacturers.

IV. Education: The Council has devoted much time to the education of the medical profession in physical therapy.

- A. By preparing standards for undergraduate and postgraduate education in physical therapy.
- B. By supplying speakers to state or county medical societies.
- C. By the Council members presenting papers before many representative medical associations in the United States.
- D. By formulating a method for extending postgraduate education.
- E. The Council has arranged for exhibits in physical therapy in conjunction with the Committee on Scientific Exhibit at the Annual Session of the American Medical Association. It has likewise presented scientific exhibits before the Association of American Railway Surgeons, American Congress of Physical Therapy, American Academy of Orthopedic Surgery, Illinois State Medical Society, Medical Society of the State of New York, Mid-South Post-Graduate Medical Assembly, Kentucky State Medical Association and the Medical Society of the State of Pennsylvania.

From the foregoing summary of past work of the Council, it can be authoritatively stated that physical therapy is now in much better repute with the entire profession than it was at the time the Council was organized. Then justifiable skepticism was warranted by the misuse of physical therapy. Today patients are receiving more and more of that type of physical therapy that is of real value to them.

V. How work is conducted:

- A. The Council has held from one to two meetings a year, and the Special Committee of the Council, consisting of three members, has met several times each year. More than 90 per cent of the work of the Council is carried on by a Bulletin sent to the members every two weeks.

VI. Future aims of the Council:

- A. There is still a great amount of work to be done, and its future activities will be directed chiefly along the lines indicated by the foregoing outline, but over a broader field. For example, the Council is undertaking the consideration of diagnostic machines, belts, supports and radium products.
- B. The Council feels that there is need for greater efforts in graduate teaching throughout the country. Therefore a more extensive plan has been developed whereby speakers may be furnished to county and state medical meetings.
- C. The Council will continue to guard zealously this field of physical therapy in order to prevent all irregular practices and to strive to enlarge its scope and usefulness for the benefit of the profession and the public at large.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary.

DIOTHANE.—Diothane Hydrochloride.—Piperidinopropanediol-di-phenylurethane hydrochloride. — $C_6H_5N.CH_2CH(OCONHC_6H_5).CH_2(OCONHC_6H_5).HCl$.—The hydrochloride of the base piperidino-propanediol-di-phenylurethane, obtained by combining piperidine and glycerol monochlorohydrin in the presence of an alkali, and reacting the piperidinopropanediol with phenyl isocyanate.

Actions and Uses.—Nearly similar to those of cocaine, but it is claimed that the anesthesia lasts somewhat longer than that induced by corresponding doses of cocaine or procaine. Its toxicity by intravenous injection is about three times that of procaine, and hence it should not be injected except in very small amounts.

Solutions prepared extemporaneously should be used promptly, since such solutions usually contain traces of alkali and are thereby subject to precipitation.

Manufactured by the Wm. S. Merrell Company, Cincinnati. U. S. patent applied for. U. S. trademark 296,850.

Diothane Ointment, 1%: An aqueous solution of diothane, 1 per cent, in an oxycholesterin base.

Diothane Solution, 1%: A solution of diothane, 1 per cent, in distilled water.

Diothane hydrochloride occurs as a fine, white crystalline, odorless powder; when applied to the tongue, it possesses a bitter taste followed by a sense of numbness; permanent in the air at ordinary temperatures; slightly soluble in water, acetone and ethyl acetate; soluble in alcohol; insoluble in benzene and ether. Its aqueous solution (1 in 100) is faintly acid to litmus. Diothane hydrochloride melts at 195 to 200 C., with decomposition. From aqueous solutions, alkali carbonates and hydroxides precipitate the free base as a colorless oil, which does not solidify under ordinary conditions.

Dissolve about 0.5 Gm. of diothane hydrochloride in 50 cc. of water; separate portions of 5 cc. each: to one portion add 5 cc. of silver nitrate

solution a white precipitate results, soluble in an excess of ammonia water, to another portion add 0.2 cc of diluted hydrochloric acid, 0.2 cc of a 10 per cent solution of sodium nitrite and gradually mix with a solution of 0.2 Gm of betanaphthol in 10 cc of a 10 per cent sodium hydroxide solution a white, changing to a yellowish and finally to an orange color appears, increasing in intensity as the concentration of the betanaphthol becomes greater (*distinction from the anesthetics responding to the diazo reaction*), to another portion add 5 drops of gold chloride solution an orange-yellow precipitate appears (*distinction from albin apothecine cocaine metcaine and nupercaine which give a lemon yellow precipitate and butyn procaine and tinctocaine, which yield brown precipitates*). Dissolve about 0.1 Gm of diothane hydrochloride in 1 cc of sulphuric acid the solution is colorless (*readily carbonizable substances*). Saturate about 0.1 Gm of diothane hydrochloride dissolved in 10 cc of water with hydrogen sulphide. no coloration or precipitation results (*salts of heavy metals*).

Dry about 0.5 Gm of diothane hydrochloride, accurately weighed, at 100 C for six hours the loss in weight does not exceed 0.5 per cent. Incinerate about 0.5 Gm of diothane hydrochloride, accurately weighed the residue is not more than 0.1 per cent. Transfer about 0.3 Gm of diothane hydrochloride, accurately weighed, to a 500 cc Kjeldahl flask, and determine the nitrogen content according to the official method described in Official and Tentative Methods of Analysis of the Association of Official Agricultural Chemists, third edition, page 20, chapter 2, paragraph 22 the percentage of nitrogen corresponds to not less than 9.5 per cent, nor more than 9.8 per cent when calculated, to the dried substance. Dissolve about 0.25 Gm of diothane hydrochloride, accurately weighed, in 25 cc of water, by warming, and transfer to a suitable Squibb separatory funnel rinse twice using about 10 cc of water followed by the addition of 3 cc of a diluted ammonia water (one part of ammonia water and ten parts of water), extract with four successive portions of ether using 20 cc each, filter through a pledget of cotton and evaporate to a thick oil in a stream of warm air, dissolve the oily residue in about 25 cc of previously neutralized alcohol, warm slightly, add 10 cc of tenth normal hydrochloric acid solution, followed by the addition of 10 cc of water, determine the excess of acid by titration with tenth normal sodium hydroxide solution, using bromophenol blue as an indicator the amount of tenth normal hydrochloric acid consumed corresponds to not less than 90.5 per cent nor more than 92 per cent of piperidinopropanediol di-phenylurethane when calculated to the dried substance. Transfer the ammoniacal aqueous portion from the foregoing immiscible solvent extraction to a 400 cc beaker and place on the steam bath for three hours, add 100 cc of water, followed by the addition of 10 cc of nitric acid and 25 cc of silver nitrate solution, subsequently boil with continuous stirring and allow to cool in a dark place. Collect the precipitate of silver chloride on a Gooch crucible, wash with diluted nitric acid and water, followed by alcohol and ether, finally dry to constant weight at 105 C, the amount of hydrogen chloride calculated from the silver chloride found corresponds to not less than 8.35 per cent, nor more than 8.45 per cent when calculated to the dried substance.

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
PAUL NICHOLAS JEECH, Secretary

THE "NOTICE OF JUDGMENT" ON SCARLET RED SALVE (HEILKRAFT MEDICAL COMPANY)

A physician recently wrote to THE JOURNAL, asking an explanation of the apparent incongruity of the Council's continued acceptance of Scarlet Red Salve (Heilkraft) after he had read the short abstract of the federal government's notice of judgment, which appeared in THE JOURNAL, July 21, 1934, page 205.

Since the product still has its accepted status in view of the firm's agreement to modify the claims which the Council, as well as the federal government, has found objectionable, no report of the Council's action (which was taken prior to receipt of the physician's inquiry) has been published. In order to clarify the apparent incongruity of the Council's continued acceptance of the product which the government has declared to be marketed under false and fraudulent therapeutic claims, the Council decided to publish the following statement of circumstances.

The following claims appearing on the label or in the package circular formed the basis of the government's action (notice of judgment 20165, June 1933) against the scarlet red salve of the Heilkraft Medical Company.

(Carton) "Causes an active proliferation of the epithelium, and in such chronic conditions as partial skin grafts ulcers following operation for infection, ulcers following burns, traumatic ulcers, specific ulcers, varicose ulcers bed sores and the like the results have been in many instances nothing short of remarkable. All who have used the agent are enthusiastic in their praise of it, (circular) In the treatment of Indolent Varicose Ulcers Sluggish or Non granulating Wounds, Sores resulting from various Blood Diseases Eczema, etc."

New and Nonofficial Remedies, 1934, contains the following statement of the actions and uses of scarlet red medicinal.

Scarlet red medicinal Biebrich and scarlet red sulphonite have a marked power of stimulating the proliferation of epithelial cells.

Opinions are divided as to the clinical value, but the dyes are used to promote the growth of epithelium in the treatment of burns, wounds, chronic ulcers, etc. In chronic ulcers, however, it is requisite that the local circulation be good in order to obtain a permanent result.

On being informed early this year of the government's action declaring Scarlet Red Salve (Heilkraft) misbranded, the Council's referee for the product made a report to the Council, which stated in part.

As some of the statements of claims come within the limits allowed by the Council's opinion according to New and Nonofficial Remedies, 1933 and others have in the past been accepted by the Council, the Council found itself in the embarrassing position of permitting the issuance of claims for a product which the Food and Drug Administration of the United States Department of Agriculture regards as "false and fraudulent."

The Food and Drug Administration was asked to assist the Council by supplying the evidence on which the Administration based its opinion. The Administration replied under date of September 28, in part, as follows:

"Our investigations lead us to believe that this preparation is sold very extensively over the drug counter to the general public and not on physicians' prescriptions or upon recommendations from physicians. The type of labeling used with this product would be considered highly extravagant when distributed by this method.

"The product was recommended as of value in ulcers following operations for infections, traumatic ulcers, specific ulcers, indolent varicose ulcers, sores resulting from various blood diseases, eczema, etc. We are of the opinion that such a label is extravagant in its claims even when recommended to a physician. A physician should be capable through his scientific training of judging the type of case in which this preparation would be of value. However, a layman is not capable of determining this. The law as written does not make any differentiation in the labels of preparations that are distributed for physicians' use or for physicians' prescriptions and those sold directly to the public."

This letter is helpful in stating the law, but it does not give the Council the benefit of a knowledge of the evidence on which the opinion of the Administration was based. In view of the possibility that the status of the therapeutic opinion may have changed since the previous referee examined the literature three years ago, the referee attempted to evaluate the published evidence.

The ability of Scarlet Red (Biebrich) to produce epithelial proliferation was first noted by Fisher in 1906. This was confirmed by others. The results of the careful experimental studies of J. S. Davis in the treatment of ulcers and skin grafts with Scarlet Red were published in the Bulletin of the Johns Hopkins Hospital 20: 186, 1909, 22: 210, 1911, 23: 332, 1912, 24: 178, 1913. These investigations still seem to the referee to prove that the chief component of Scarlet Red, aminoazotoluol, stimulates epithelial proliferation. The referee does not know of any refutation of the work of Fisher, Davis and others. The referee abstracted about ten papers published during the past five or six years reporting good results in treatment of ulcers with Scarlet Red or similar compounds. There has been no experimental work comparable in scope and care with the earlier work. The status of therapeutic opinion, however, does not seem to have changed, if the published papers are an index of that opinion.

It is to be recalled that New and Nonofficial Remedies contains the admission that clinical opinion is divided on the question of the therapeutic value of Scarlet Red. It is obvious also that the Heilkraft Medical Company was at fault in mentioning diseases by name in the trade package circular. The Council readily concurs in the opinion of the Food and Drug Administration that it is extravagant to claim that Scarlet Red can cure ulcers due to serious underlying constitutional or local diseases. The necessity of adequate local circulation is admitted in New and Nonofficial Remedies in connection with the treatment of chronic ulcers and it is obvious that syphilitic ulcers will not be cured by Scarlet Red. The Council believes that the Food and Drug Administration may not regard as "false and fraudulent" the claim that Scarlet Red stimulates epithelial proliferation unless it has at its disposal undisclosed experimental evidence better than that of Davis and others. It appears that the firm has gone beyond justifiable limits in its specific and unqualified claims. It seems therefore, that an agreement may be reached on these questions by the three parties concerned by adhering to the conservative statement in New and Nonofficial Remedies.

In transmitting this report to the Heilkraft Medical Company, the Council stated that it would reaccept the firm's product for inclusion in New and Nonofficial Remedies only on condition that the labels and advertising are revised along the following lines: (1) limitation of claims to the stimulating effect of Scarlet Red on epithelial cells, and (2) omission of unqualified claims of benefit in the treatment of traumatic ulcers, infected ulcers, and ulcers associated with systemic disease. The firm has agreed to revise its labels and advertising material in the very near future, in accordance with the stipulations of the Council's report.

Committee on Foods

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION, AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION. **RAYMOND HERTWIG, Secretary.**

Licenses.—Krim-Ko Company, Chicago, manufactures the Krim-Ko Chocolate Flavored Drink Base, and licenses its use, the name Krim-Ko, and standard advertising under definite contract conditions.

Description.—Pasteurized chocolate flavored sweetened skim milk; contains skim milk (from 0.5 to 1.5 per cent milk fat), sucrose, chocolate and cocoa, tapioca flour, salt and traces of tartaric acid and agar; flavored with imitation vanilla extract. See Krim-Ko Chocolate Flavored Drink, *THE JOURNAL*, June 30, 1934, page 2187.

CHALLENGE BUTTER

Distributor.—Challenge Cream & Butter Association, Los Angeles.

Description.—Packaged, salted, pasteurized butter graded to rate 92 or 93 score by United States Department of Agriculture graders.

Manufacture.—The cream used is largely separated out at the creameries and not on the farms. It is tested for milk fat, acidity, flavor and odor, is pasteurized for thirty minutes at 66 C. and cooled to churning temperature, or, if held over night, chilled below churning temperature. In winter, the maximum acidity (as lactic acid) permitted is 0.2 per cent, in summer 0.25 per cent. Certified food color is added when necessary to maintain a uniform butter color throughout the year. The cream is churned under standard conditions of time and temperature. The buttermilk is drawn off. The butter is washed with water, salt is added and the butter is thoroughly worked to distribute the salt and produce a moisture content of from 16 to 16.5 per cent. Before the butter is removed from the churn it must contain by analysis less than the specified maximum moisture and salt content. The butter is packed at the various creameries either in 68 pound cubes or in packing molds and is shipped under refrigeration to the packaging plants, where it is graded, cut to standard size, wrapped and packed in cartons.

No butter flavors or starters are used. Only occasionally is a neutralizer (sodium bicarbonate) used.

A premium is paid for butter scoring 93. Only 92 to 93 score butter is used for this brand. The grading is done by United States Department of Agriculture graders. The churns are treated with boiling water whenever necessary to destroy micro-organisms that may establish themselves. Code marks on the packages identify the batch of butter, date of churning and packing and the creamery. Laboratory control is maintained to assure that all butter issuing under the brand named "Challenge" fulfils specified requirements.

Analysis (submitted by distributor).—

	(1)	(2)	(3)
Moisture	16.4%	14.5%	16.0%
Milk fat.....	80.6	82.4	80.7
Curd	0.9	1.1	0.8
Sodium chloride.....	2.1	2.0	2.4

Calories.—From 7.3 to 7.4 per gram; from 207 to 210 per ounce.

LIBBY'S NATURAL HAWAIIAN PINEAPPLE JUICE

Manufacturer.—Libby, McNeill & Libby, Chicago.

Description.—Hawaiian pineapple juice, retaining in high degree the natural vitamin content.

Manufacture.—Fully matured and sound Hawaiian pineapples are sized to cylindric shape by a revolving cylindric knife, which removes the outer peel; the two ends are mechanically cut off. Any remaining particles of peel are removed by hand. The trimmed pineapples are washed by water sprays and crushed. The pulp is heated and the juice is expressed in a continuous press in an atmosphere of steam, screened, canned, and pasteurized at a definite temperature and for a time sufficient to insure keeping quality.

The preparation and processing are under laboratory supervision. All employees handling pineapples wear rubber gloves, aprons and caps.

Analysis (submitted by manufacturer).—

	per cent
Moisture	84.1
Ash	0.4

SATURDAY, DECEMBER 8, 1934

BACTERIOPHAGE THERAPY

Bacteriophage preparations have been available to the medical profession for about fifteen years. Some have been offered cautiously under moderate claims; other preparations have been exploited with promulgation of d'Herelle's idea that bacteriophage is a living parasite of bacteria, a sort of vital germicide. A few bacteriophage preparations have been submitted to the Council on Pharmacy and Chemistry, but none have been accepted for inclusion in New and Nonofficial Remedies. Hundreds of papers have been published on the clinical use of bacteriophage products, many of which were made in noncommercial laboratories. What may be said fairly about the composition of these products, the nature of their constituents and the results to be expected from their therapeutic application? The first section of a critical review of the principles and results of the use of bacteriophage infections is published elsewhere in this issue of *THE JOURNAL*.¹

The discoveries of Twort and d'Herelle in 1915 and 1917 that bacteria can be dissolved and destroyed by an apparently self-propagating lytic principle were of great importance. Investigations of the nature and actions of this ultramicroscopic, filtrable agent have developed significant information. Uncertainties as to the nature of the material and unwarranted claims for its therapeutic efficacy should not be allowed to cloud the appreciation of its biologic importance.

Two views prevail as to the nature of the lytic principle. d'Herelle has held that it is a living parasite of bacteria, an ultramicroscopic filtrable virus, growing and multiplying in the process of changing or dissolving bacteria. He and his associates have supported this opinion with ingenious experiments and shrewd analogies to filtrable viruses. d'Herelle does not seem to have proved his point, but his hypothesis has not yet been disproved. Other investigators believe that the lytic principle is an inanimate substance of an enzyme-like character, which is reproduced during the

course of bacterial autolysis. The difficulty in making crucial experimental tests of these hypotheses comes from the fact that the lytic principle cannot be propagated apart from the living bacteria on which it acts. The weight of opinion, however, now seems to be preponderantly on the side of the argument that the lytic principle is inanimate. Since it has not been proved that the bacteriophage is a living agent and since there is good evidence opposed to the opinion that it is an autonomous agent, claims that it is a "vital germicide" are unwarranted.

The complexity of the "bacteriophage" mixtures is one cause of the confused and contradictory publications. The usual material called bacteriophage is made by allowing lysis to proceed to completion in a young growing broth culture of some bacterium. This is then filtered through a Berkefeld, Mandler or Seitz filter. Sometimes a preservative is added (often to the detriment of the lytic principle). This material then contains (1) the lytic principle or bacteriophage, (2) products of the dissolved bacteria, (3) products of bacterial metabolism, and (4) constituents of the culture medium. In its clinical application, the possible effects of all these constituents must be taken into consideration.

The action of the lytic principle on cultures on plates and in test tubes is undoubtedly far greater than its action on bacteria in the animal body. Blood, pus, bile, urine and other secretions of the body inhibit or annul its ability to dissolve micro-organisms. There is no evidence that lysis or killing of bacteria by bacteriophage occurs in vivo, except possibly in the bladder and walled off spaces, where little exudate is present and where irrigation with large amounts of lytic filtrate can be used. As for its other possible effects on invading bacteria, the evidence is incomplete. By opsonizing bacteria, it may aid in phagocytosis. By causing bacterial variation it may lead to the appearance of less virulent races of the infecting germ, or it may stimulate the appearance of more virulent varieties.

The lytic filtrates have a variety of specificities; some are strictly specific for one type of micro-organism, others affect numerous kinds of related bacteria. Obviously, if any specific therapeutic results are to be obtained, a lytic principle capable of acting on the bacterium causing the infection should be used. To accomplish this purpose, bacteriophages have been prepared against organisms isolated from patients. More often stock preparations of polyvalent bacteriophages or artificial mixtures of several bacteriophages have been applied. In numerous therapeutic trials the capacity of the lytic principle to dissolve the infecting organism in vitro has not been tested, although this is a phase of the clinical use of these materials that should never be neglected.

The products of the dissolved bacteria are excellent antigens. They are good vaccines. They stimulate the production of antibodies and they bring about states of resistance after their injection into the body. The

1. Eaton, M.D., and Bayne-Jones, Stanhope: Bacteriophage Therapy, this issue, p. 1769.

products of bacterial metabolism and constituents of the culture medium, together with the solution of bacterial substance, may have nonspecific protective actions like the effects of nonspecific protein therapy. In fact, the favorable results accredited to bacteriophage therapy may have been due entirely to the specific immunizing action of bacterial proteins in the material used and to nonspecific effects of the broth filtrates.

In this connection it is necessary to mention the so-called antiviral, which is claimed by some manufacturers to be a valuable constituent of these complex mixtures. "Antiviral" is not an antibody in the usual sense. It is a name given by Besredka to some presumed product of bacterial growth, which is supposed to unite with the susceptible receptors of body cells and, by occupying them inertly, prevent a subsequent attachment or attack by the living bacteria. Besredka's views have not been substantiated and there is no convincing evidence that lytic filtrates to which "antiviral" has been added are any more or less effective than the usual filtrates.

Almost every infectious condition from colitis to rhinitis has been treated with bacteriophage. Few controlled clinical studies have been made, and the published reports of the results of all the trials are, on the whole, contradictory. Only in the treatment of local staphylococcal infections and perhaps in cystitis due to colon bacilli and staphylococci has even slightly convincing evidence been presented to show that therapy with lytic filtrates is effective.

A multitude of complexities have been concealed under the simplified terminology of the "bacteriophage metaphor." From these writings there emerge the possibilities that the lytic principle, functioning as an inert substance rather than a living agent, may under certain conditions in the body dissolve bacteria, induce bacterial variation and increase phagocytosis. The chief action of the lytic filtrates appears to be an immunizing action, so that bacteriophage therapy would appear to be essentially a form of vaccine therapy.

RESPIRATORY RESPONSE TO ALTITUDE

The organism is so delicately equilibrated with the environment that any disturbance in its surroundings is followed by changes the magnitude and order of which have long interested physiologists. One naturally thinks of the alterations in temperature to which the body is exposed; the chemical and physical responses to this circumstance are more or less well known. With the development of aviation during the World War and later in a commercial way, more attention has been devoted to the train of events occurring in the organism when high altitudes are reached. The physiologic consequences of the adaptation, so far as they are known, are surprisingly widespread; they include changes in the respiration, in the circulatory mechanism and in the blood itself, all of considerable magnitude. As to the

immediate cause of this extensive disturbance, one authority¹ in this field has stated that "most of the bodily changes observed at high altitudes can be directly or indirectly attributed to the relative shortage of oxygen." A complete description of the effects of oxygen want produced by actual ascent to high altitudes or by experimental means in a low pressure chamber provides a striking example of functional integration in the organism.

Perhaps the most immediately appreciated response to a lowered pressure of oxygen is in the respiration.

In a recent study, Hurtado, Kaltreider and McCann² have corroborated older observations and added new ones. Three human subjects were exposed in a low pressure chamber to air at a pressure of 419 mm. of mercury, corresponding to an altitude of 16,400 feet. This level of pressure was reached in fifteen minutes and was maintained for two hours. Care was taken to change the air completely at frequent intervals, and accumulation of carbon dioxide was prevented. In common with previous experience, the volume of air breathed per unit of time was increased slightly in two of the subjects with little change in either the rate or the depth of breathing. In airplane flights to high altitudes, the increase in depth of breathing is frequently so gradual and so small in amount that the pilot is unaware of the change; more than one has become unconscious before warned to take oxygen by the subjective sensations. Alveolar air shows a decreased tension of both oxygen and carbon dioxide, a response observed in most persons. When this fails to occur, mountain sickness follows. In the Rochester experiments all three subjects showed a diminution of the vital capacity, a rather constant finding in such studies, and a somewhat greater relative increase in residual air.

Guinea-pigs were killed after two hours in the low pressure chamber and the lungs examined grossly and microscopically. There was pronounced congestion, which was obvious to the naked eye; histologic study revealed dilatation of the capillaries, which in turn resulted in a thickening of the alveolar wall. In the central parts of the lung, many of the alveolar spaces were obliterated. This is of interest in view of the remarkable series of studies on blood flow in the pulmonary capillaries recently reported by Wearn and his associates.³ By direct observation of a portion of the immobilized lung of anesthetized cats, they saw capillaries disappear and others appear spontaneously in a field without active circulation before. Blood flowed intermittently in the arterioles and capillaries of the lung, and frequently a spontaneous reversal of the direction of flow was seen. The conclusion was reached that normally the average number of active

1. Schneider, E. C.: *Yale J. Biol. & Med.* 4: 537 (March) 1932.

2. Hurtado, Alberto; Kaltreider, N. L., and McCann, W. S.: *Am. J. Physiol.* 109: 626 (Oct.) 1934.

3. Wearn, J. T.; Ernestine, A. C.; Bromer, A. W.; Garr, J. S.; German, W. J., and Zschiesche, L. J.: *Am. J. Physiol.* 109: 236 (Aug.) 1934.

capillaries represents only a small portion of the available capillaries per sac. Acute asphyxia did not cause the capillaries or arterioles to open. In the Rochester experiments, on the other hand, the dilatation of the capillaries of the lung was brought about by relative lack of oxygen induced gradually and arose as a compensatory response to the resulting anoxemia. The changes in the lungs likewise account for the observed reduction in vital capacity associated with the decreased pressure of oxygen.

Among other responses by the body to altitude there is an increase in the oxygen-transporting mechanism. There is an increase in the number of red corpuscles and therefore of hemoglobin. One of the significant observations made by Hurtado and his co-workers was a reduction in the saturation of hemoglobin with oxygen at the low pressure; there were in two subjects changes from 99.7 and 95.3 per cent saturation to 68.3 and 74.0 per cent, indicating a pronounced degree of anoxemia. There are important physiologic questions involved in a study of the widespread respiratory response to low pressures of oxygen; in the days to come, when private motor cars and airplanes make ascents to moderate or greater altitudes, the question of the functional disturbances and their rational treatment will become one of considerable practical significance.

TRYP SOGEN-CARNRICK

Knowledge of the glands of internal secretion is at best fragmentary. Nevertheless, as our readers well know, a number of manufacturers have been for years promoting elaborate lists of polyglandular preparations for the treatment of innumerable diseases. One of those most persistently promoted is a product called "tryp-sogen," prepared by the G. W. Carnrick Company, Newark, N. J. Even today, notwithstanding the vast amount of research that has been published on the treatment of diabetes, this company continues to recommend this product as "a valuable therapeutic agent" in the treatment of this disease. Over the years, the product called "tryp-sogen" has had a variety of formulas. Once even such inorganic compounds as gold bromide and arsenic bromide were included in it. Its name implies that this product is a precursor of trypsin, which is formed by the action of succus entericus on trypsinogen. In 1913 it was claimed that the preparation consisted of the enzyme of the islands of Langerhans with the tryptic and amylolytic ferments of the pancreas. At that time the gold and arsenic salts were still in the preparation. Later it was claimed that "tryp-sogen supplies the special internal secretory substance elaborated by the body itself for the control of normal carbohydrate metabolism as well as the special pancreas proteins and amino acid complexes necessary for a regenerative effect on the patients' own defective pancreas."

It has never been demonstrated that tryp-sogen contains insulin, yet insulin is, of course, "the special internal secretory substance" that controls normal carbohydrate metabolism. Even if this product did contain insulin, however, there is no evidence that it is effective on oral administration. In fact, just the opposite has been proved.

THE JOURNAL has repeatedly called the attention of the medical profession to the fallacious character of these claims, yet the firm never loses heart; presumably because it is able to find enough doctors who are willing to believe its claims to make its advertising worth while. One need not condemn the product, however, merely on its irrational basis. As long ago as 1907, Tyson¹ stated that he had a patient who took "\$25 worth of tryp-sogen tablets without any effect whatever." His experience has been verified repeatedly. Not satisfied, however, with the money it extracts from patients with diabetes, the firm has recently suggested the use of the product "as an adjunct in hypertension." Obviously there is not the slightest scientific evidence to indicate that it has merit in hypertensive disorders.

Years ago there might have been some slight excuse for the use of pancreatic extracts given by mouth in diabetes. Today such use is ignorant, unscientific and absolutely without warrant. The doctor who gives such preparations by mouth to the exclusion of the well established and effective methods of treatment involving proper control of the diet and the use of insulin might well be charged with failing to give his patient the ordinary scientific care expected from any average physician in such a condition. The physician who uses these products allies himself definitely with the promoter in a form of malpractice that might result most seriously for the patient concerned.

Current Comment

AGED PHYSICIANS

In compiling the current issue of the American Medical Directory, some interesting notes were collected relative to physicians of advanced age, many of whom are still in practice. The names of ten doctors were collected who were born between 1828 and 1838, so that the oldest of these men is 106 years of age and the youngest 96. They graduated in medicine from the years 1852 to 1878. Of the four men who are still in practice, the years of practice vary from eighty-one to sixty-nine. These are, of course, remarkable. It is significant that by far the majority of these men of advanced years live in small communities. THE JOURNAL is interested in receiving records of physicians who are more than 95 years of age.

1. Tyson, James. Treatment of Diabetes Mellitus, J. A. M. A. 49:1583 (Nov. 9) 1907.

Association News

MEDICAL BROADCASTS Columbia Broadcasting System

The American Medical Association broadcasts on a western network of the Columbia Broadcasting System each Thursday afternoon on the Educational Forum from 4:30 to 4:45, central standard time. The next three broadcasts will be as follows:

- December 13. Shopping for Health, W. W. Bauer, M.D.
- December 20. Social Security, Morris Fishbein, M.D.
- December 27. Budgeting for Health, W. W. Bauer, M.D.

National Broadcasting Company

The American Medical Association broadcasts under the title "Your Health" on a Blue network of the National Broadcasting Company each Tuesday afternoon from 4 to 4:15, central standard time. The next two broadcasts will be as follows:

- December 11. Care of the Handicapped, Morris Fishbein, M.D.
- December 18. Fight Tuberculosis With Modern Weapons, W. W. Bauer, M.D.
- December 25. Holiday; no broadcast.

THE ATLANTIC CITY SESSION

Chairmen of Section Committees to Assist in Promotion of Section Exhibits

The fifteen sections of the Scientific Assembly have appointed exhibit committees to assist in the promotion of section exhibits at the Atlantic City session and in the coordination of activities between the Scientific Assembly and the Scientific Exhibit. Chairmen of the section exhibit committees are as follows:

PRACTICE OF MEDICINE:

Irving S. Wright, New York.

SURGERY, GENERAL AND ABDOMINAL:

Alton Ochsner, New Orleans.

OBSTETRICS, GYNECOLOGY AND ABDOMINAL SURGERY:

H. C. Hesselstine, Chicago.

OPHTHALMOLOGY:

Georgiana Dvorak-Theobald, Oak Park, Ill.

LARYNGOLOGY, OTOTOLOGY AND RHINOLOGY:

William V. Mullin, Cleveland.

PEDIATRICS:

F. Thomas Mitchell, Memphis, Tenn.

PHARMACOLOGY AND THERAPEUTICS:

C. D. Leake, San Francisco.

PATHOLOGY AND PHYSIOLOGY:

Frank W. Hartman, Detroit.

NERVOUS AND MENTAL DISEASES:

Groves B. Smith, Godfrey, Ill.

DERMATOLOGY AND SYPHILOLOGY:

Fred D. Weidman, Philadelphia.

PREVENTIVE AND INDUSTRIAL MEDICINE AND PUBLIC HEALTH:

Paul A. Davis, Akron, Ohio.

UROLOGY:

Russell S. Ferguson, New York.

ORTHOPEDIC SURGERY:

Paul N. Jepson, Philadelphia.

GASTRO-ENTEROLOGY AND PROCTOLOGY:

A. H. Aaron, Buffalo.

RADIOLOGY:

S. W. Donaldson, Ann Arbor, Mich.

Application blanks for space in the Scientific Exhibit may be obtained from any of the foregoing chairmen, or from the Director, Scientific Exhibit, 535 North Dearborn Street, Chicago.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST: SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARIZONA

Personal.—Dr. Hugh A. Rasmussen, Westby, Wis., has been appointed medical officer for the Pima Indian Agency near Phoenix.—Dr. Louis C. B. Baldwin, Phoenix, formerly assistant professor of medicine, University of Rochester School of Medicine, Rochester, N. Y., has been appointed physician-in-chief of the Desert Sanatorium and Institute of Research, Tucson.

CALIFORNIA

Personal.—Dr. Harper Peddicord, Redwood City, has been appointed health officer of San Mateo County to succeed Dr. Harold E. Morrison. Dr. Frank H. Folkins is health officer of Redlands, succeeding Dr. Harold G. Gentry and Dr. Perryman F. Page Jr., health officer of Taft, succeeding Dr. Oran Newton.

Professor Anrep to Give Lane Lectures.—Dr. Gleb V. Anrep, professor of physiology, Egyptian University, Cairo, Egypt, will deliver the 1935 series of Lane Lectures at Stanford University School of Medicine, April 22-26. The five lectures will cover various phases of "Regulation of the Cardiovascular System." The Lane lectures were established in 1896 by Dr. Levi Cooper Lane, San Francisco, the founder of Cooper Medical College, which in 1908 became the school of medicine of Leland Stanford Junior University. Every two years some physician or scientist who has made a definite contribution in the field of medicine is invited to give a free course of lectures for medical students and the medical profession at large.

CONNECTICUT

Fellowships for Study of Adolescence.—Yale University School of Medicine announces the establishment of five fellowships by the Rockefeller Foundation for the study of adolescence, which will be approached through studies of anatomy, physical anthropology and anthropometry; physiology, biochemistry and nutrition; psychology and psychiatry; medicine, particularly pediatrics and immunology, and education and social adjustments. It is hoped to discover the methods by which data can be obtained on the growth and development of individuals during the second decade of life. The medical school has also effected a working relationship with the university department of physics. Appointments are to be for two years and they are to expire in alternate years so that one of the two men will always have had one year's experience on the project.

DELAWARE

Health at Wilmington.—Telegraphic reports to the U. S. Department of Commerce from eighty-six cities with a total population of 37 million, for the week ended November 24, indicate that the highest mortality rate (18.6) appears for Wilmington and the rate for the group of cities as a whole, 11.3. The mortality rate for Wilmington for the corresponding period last year was 10.8 and for the group of cities, 11.5. The annual rate for eighty-six cities for the forty-seven weeks of 1934 was 11.3 as compared with a rate of 10.9 for the corresponding period of the previous year. Caution should be used in the interpretation of these figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits or that they have a large Negro population may tend to increase the death rate.

DISTRICT OF COLUMBIA

Medical Bureau for the Needy.—Creation of a medical admitting bureau in Washington for persons seeking free medical care has been endorsed by the Medical Society of the District of Columbia. It is proposed that the bureau be operated in cooperation with the Community Chest and handle all applications for free treatment at medical clinics or for free hospital care. The plan endorsed by the society calls for a special supervising committee, consisting of members from the executive committee of the Community Chest, the hospital superintendents' association and the medical and dental societies.

ILLINOIS

Conference of Health Officers.—The annual conference of Illinois health officers and public health nurses will be held in the Centennial Building, Springfield, December 11-12. The following program will be presented:

- Dr. David J. Davis, Chicago, The Medical College and Preventive Medicine.
 Dr. Wilson G. Smillie, Boston, Practical Epidemiology.
 Dr. David O. N. Lindberg, Decatur, Case Finding in a Tuberculosis Program.
 H. J. Shaughnessy, Ph.D., Springfield, The Laboratory and Epidemiology.
 Pearl McIver, R.N., Washington, D. C., Community Coordination for a Public Health Nursing Program.
 Eva F. MacDougall, R. N., Indianapolis, Qualities for Success in a Public Health Nurse.
 Dr. Earl E. Kleinschmidt, Ann Arbor, Mich., A Philosophy of Health Education.
 Dr. Warren F. Draper, Washington, D. C., Administrative Practice in Public Health.
 Dr. Herman N. Bundesen, Chicago, Popularizing Preventive Medicine.
 Dr. Sidney O. Levinson, Chicago, Convalescent Serum in Infantile Paralysis.
 Dr. Archibald L. Hoyne, Chicago, Convalescent Serum in Scarlet Fever.
 Dr. Joseph A. Baudouin, Montreal, Vaccination in Control of Tuberculosis.
 Dr. Clifford G. Grulee, Chicago, Breast Feeding as a Factor in Preventive Medicine.
 Dr. Winston H. Tucker, Springfield, Epidemic Encephalitis.
 Dr. Albert S. Gray, Hartford, Conn., Newer Phases of Occupational Hazards.
 Dr. Lloyd L. Arnold, Chicago, Practical Control Methods in Syphilis.

Chicago

Dr. Flexner to Give Pasteur Lecture.—Dr. Simon Flexner, director of laboratories, Rockefeller Institute of Medical Research, New York, will deliver the thirteenth Pasteur Lecture of the Institute of Medicine of Chicago, April 26. His subject will be "Virus Diseases of the Central Nervous System: Their Extent and Mode of Infection."

General Practitioner's Night.—"Acute Coronary Thrombosis" will be the theme of the meeting of the Chicago Medical Society, designated "General Practitioner's Night," December 12. Speakers will be Drs. Laurence E. Hines, James G. Carr, Chauncey C. Maher, Don C. Sutton and Sidney Strauss. The society sponsored a lay educational program, December 5. Dr. William A. O'Brien, associate professor of preventive medicine and public health and pathology, University of Minnesota School of Medicine, Minneapolis, presented "The Story of Cancer" and Dr. Morris Fishbein, editor of THE JOURNAL, "Cancer Charlatans."

Society News.—Speakers before the Chicago Society of Internal Medicine, November 26, were Drs. Rudolph Schindler on "Gastroscopy—Present Status and Value in Diagnosis of Gastric Disease"; James G. Carr, "Clinical Experiences with a Derivative of Squill," and Joseph L. Miller, "Recent Advances in Our Knowledge of the Thyroid Gland."—At a meeting of the Chicago Laryngological and Otological Society, December 3, Dr. John Gordon Wilson presented "A New Approach to the Study of Otosclerosis"; Austin A. Hayden, "Otolologists and Leagues for the Hard of Hearing," and Miss Gertrude Torrey, "Application of Lip Reading to Cases of Progressive Deafness."

Conference on Birth Control.—A conference on the scientific, practical and ethical aspects of the Ogino-Knaus method of birth control will be held in the Cameo Room of the Morrison Hotel, December 10, at 8 o'clock, under the auspices of the Catholic Physicians' Guild of Chicago. The following program will be presented:

- Dr. Andrew C. Ivy, professor of physiology, Northwestern University Medical School, The
 Dr. Arthur G. Miller, director of the Mill an
 illustrated demonstration of the validity of the Ogino-Knaus method from 154 clinical cases.
 Rev. John A. O'Brien, professor in the Newman Foundation and chaplain of the Catholic students, University of Illinois, Lawful Birth Control in Harmony with Science and Ethics.

Participating in the formal discussion will be

- Dr. Anton J. Carlson, chairman, department of physiology, University of Chicago.
 Dr. Frederick H. Falls, professor of gynecology and obstetrics, University of Illinois College of Medicine.
 Dr. Mark T. Goldstone, chief of medical and surgical staffs, Wesley Memorial Hospital.
 Dr. N. Sproat Heaney, clinical professor of gynecology and obstetrics, Rush Medical College.
 Dr. Henry Schmitz, professor and head of the department of gynecology of Loyola University.
 Dr. Irving F. Stein, president, Chicago Gynecological Society.

An invitation is extended to members of the Chicago Medical Society and to out of town physicians and scientists interested in the problem of birth control.

IOWA

Executive Secretary Resigns.—Mrs. Dorothy C. McCarthy has resigned as executive secretary of the Iowa State Medical Society, effective November 1. Miss Dorothy M. Nelson has been named acting executive secretary. The position was created at the annual session of the state society in 1933, and Mrs. McCarthy was the first incumbent.

Society News.—Dr. Vernon C. David, Chicago, discussed pathology and treatment of some lesions of the colon and rectum before the Black Hawk County Medical Society in Waterloo, October 16.—Dr. Victor E. Levine, Omaha, discussed the classification and treatment of the anemias before the Cerro Gordo County Medical Society in Mason City, October 9.—Dr. Frederick J. Swift, Des Moines, of the state health department, addressed the Clinton County Medical Society, November 1, on public health activities.—The Dallas-Guthrie Medical Society was addressed in Panora, October 18, among others, by Dr. Percival B. Glew, Dallas Center, on "Salivary Calculi."—Dr. Nathaniel G. Alcock spoke before the Johnson County Medical Society in Iowa City, October 3, on transurethral prostatic resection.—A symposium on sanitation was presented before the Marion County Medical Society in Pella, October 12, by Dr. Carl Aschenbrenner, C. J. Scott, D.V.M., and T. G. Fultz, D.V.M.—Dr. Clinton E. Harris, Woodmen, Colo., addressed the Poweshiek County Medical Society in Grinnell, October 10, on tumors of the chest.

MASSACHUSETTS

Collection of Photographs of Ophthalmologists.—A collection of photographs begun by the late Dr. Lucien Howe forms the nucleus of a gallery now being assembled at the Howe Laboratory of Ophthalmology, Boston, under the direction of Mrs. Howe. A large part of the collection are photographs of the chairmen of the Section on Ophthalmology of the American Medical Association. This group of fifty-three photographs, most of which are autographed, were collected by Dr. George S. Derby and, following his death, in compliance with his wish, were given to the laboratory. The founders of the American Ophthalmological Society, Drs. Freeman J. Bumstead, Hasket Derby and Henry D. Noyes, constitute a second group. Included also are photographs of Drs. Edward Reynolds and John Jeffries, who established the Massachusetts Eye and Ear Infirmary in 1824; Dr. Elisha North, founder in 1817 of the New London Eye Infirmary, the first institution of its kind in the United States; Drs. Edward Delafield and John K. Rodgers, founders of the New York Eye Infirmary in 1820; Dr. Philip Syng Physick, who established the Pennsylvania Infirmary for Diseases of the Eye and Ear in 1822; Dr. George McClellan, founder of the Institution for Diseases of the Eye and Ear in Philadelphia, 1821, and Dr. Edward L. Holmes, one of the founders of the Illinois Charitable Eye and Ear Infirmary in 1858. Eleven countries are represented in the collection of 125 photographs, but there is as yet no grouping on that basis. Dr. Howe died in Belmont in 1928. He was chairman of the Section on Ophthalmology of the American Medical Association, 1895-1896; emeritus professor of ophthalmology, University of Buffalo School of Medicine, and past president of the American Ophthalmological Society. He was responsible for the so-called Howe Law in 1890, which was the first law for the prevention of ophthalmia neonatorum by providing for the use of prophylactic drops in infant's eyes. In 1926 he gave \$250,000 to Harvard University to establish the Howe Laboratory of Ophthalmology, of which he was the director. He was awarded the Leslie Dana Gold Medal in 1927.

MINNESOTA

Cosmetician's Claims Unwarranted.—The state board of medical examiners has warned Mrs. Ella Graham, Maple Lake, that she must refrain from representing herself as a skin specialist. Mrs. Graham has been traveling about the state taking orders for cosmetics, and an investigation was made following her visit to Anoka, where she is said to have represented herself as a skin specialist.

Society News.—Speakers before the Minnesota Academy of Medicine, November 14, were Drs. Frank E. Burch, St. Paul, and Martin Nordland, Minneapolis, on "Surgical Treatment of Retinal Detachment" and "Hyperthyroidism in Children," respectively.—Speakers before the Clay-Becker County Medical Society at Lake Park, November 2, were Drs. Jay Arthur Myers, "Diagnosis, Treatment and Prevention of Tuberculosis"; Harold S. Diehl, "The Common Cold," and Ralph V. Ellis, "Diagnosis and Treatment of Hay Fever."—At a meeting of the Hennepin County Medical Society, November 5, Drs. Rev-

ben A. Johnson and Hobart A. Reimann discussed "Micrococcus Tetragenus Infection" and "Recent Advances in the Specific Therapy of Pneumonia," respectively. Dr. Thomas M. Rivers, New York, addressed the society, November 21, on encephalitis.

MISSOURI

Fifty Years in Practice.—Twenty-six members of the St. Louis Medical Society were honored at a meeting, November 27, in commemoration of the completion of fifty years or more in the practice of medicine. Rabbi Julius Gordon was the speaker; the title of his talk was "A Minister Looks at Medicine." The guests of honor were:

Carl Berek	George A. Humpert
Louis C. Boisliniere	Bransford Lewis
Henry S. Brookes	Heine Marks
James A. Dickson	Fred W. Patton
Meyer J. Epstein	Anand N. Ravold
William A. Fries	Francis L. Reder
Francis R. Fry	Henry Schwarz
Joseph Grindon	George N. Seidlitz
Moses E. Haase	Max C. Starkloff
Willis Hall	Paul F. Vasterling
Eugene F. Hauck, Clayton	John W. Vaughan
Louis Hauck	Benjamin A. Wilkes, Los Angeles
Moses W. Hoge	Henry L. Wolfner

NEW YORK

Society News.—Dr. William A. Sawyer, Rochester, was elected president of the Tuberculosis and Health Association of Rochester and Monroe County at a meeting, October 24. Philip P. Jacobs, Ph.D., of the staff of the National Tuberculosis Association, New York, conducted a tuberculosis institute the same day under the auspices of the county, state and national organizations, with the cooperation of Rochester health and social agencies.

New York City

The Sir Robert Jones Lecture.—Dr. Philip D. Wilson, surgical director of the Hospital for Ruptured and Crippled, delivered the fifth Sir Robert Jones Lecture at the Hospital for Joint Diseases, December 6, entitled "What Can Orthopedic Surgery Do for the Arthritic Cripple?"

Study of Appendicitis.—At a combined meeting of the section on medicine and surgery of the New York Academy of Medicine, December 7, Dr. Shepard Krech made a report on a two years study of acute appendicitis, conducted at the request of the academy in fourteen hospitals. The operative mortality of acute appendicitis was found to be 7 per cent in 1921 and the same in 1931. At a recent meeting of the academy, it was voted that the committee on public health relations make a further study along the lines of the recent study of maternal mortality.

Professor Urey Receives Nobel Prize in Chemistry.—Harold C. Urey, Ph.D., associate professor of chemistry, Columbia University, has been honored with the Nobel prize in chemistry for 1934 for his discovery of double weight hydrogen. Dr. Urey, a native of Indiana, took his baccalaureate degree in zoology at the University of Montana and his advanced degree in chemistry at the University of California in 1923. He is the editor of the *Journal of Chemical Physics* and co-author of "Atoms, Molecules and Quanta." Dr. Urey last April received the Willard Gibbs Medal of the Chicago section of the American Chemical Society.

Applicants for Free Medical Services.—More than 2,000 names of persons seeking free or partly free health and welfare services were cleared each day through the Social Service Exchange during the fiscal year from Oct. 1, 1933, to Oct. 1, 1934, according to the annual report. The total number of names cleared during the year was 634,984, as compared with 712,428 for the corresponding period of 1932-1933. Almost half the number, 328,967, were known to one or more social agencies in the city. The exchange is a cooperative activity carried on under the auspices of the Welfare Council for more than 500 health and welfare organizations in order to make their services quickly available.

Hospitals Protest Taxation.—The nonmunicipal hospitals of New York have suffered severe hardship through new state and federal statutes that impose indirect taxes, the Hospital Information and Service Bureau asserted in its annual report to the United Hospital Fund. All voluntary hospitals were compelled to pay the sales tax, which was put into effect in New York May 1, 1933. They must also pay processing taxes on cotton, wheat, corn, pork products and certain paper products, but they are entitled to a refund on the percentage of goods that is used exclusively for the care of the poor. Other problems that beset the hospitals in their efforts to lower maintenance costs are lack of relief funds to help defray cost of free care, underpayment by the city for public charges, and

the proposed eight hour day for nurses. Nine convalescent homes were forced to close during the past year, depriving the city of 305 beds, the bureau reported. Dr. Charles Gordon Heyd is chairman of the hospital information bureau and E. H. Lewinski-Corwin, Ph.D., is director. The United Hospital Fund opened its annual campaign for funds, November 26. It seeks to raise \$500,000.

OREGON

Society News.—The Polk-Marion-Yamhill Counties and Central Willamette medical societies held a joint meeting at Newport, September 22, at which the following scientific program was presented: Drs. James C. Masson, Rochester, Minn., on "Use of Living Sutures in the More Difficult Abdominal Hernias" and "Malignancy of the Large Bowel"; John M. Blackford, Seattle, "Hypertension"; Hale A. Haven, Seattle, "Surgical Relief of Pain," and Albert W. Holman, Portland, "Nephritis."

Guest Home for Psychoneurotic Patients.—Announcement is made of the opening in Portland of the Northwest Retreat, a guest home for convalescent or psychoneurotic persons, under the direction of Dr. James L. McCartney, until recently psychiatrist on the staff of the New York State Department of Corrections. Preference will be given to persons in a cooperative state in which a favorable result may be expected. The Retreat will be conducted as a private residence. Persons interested in the understanding of psychiatry and mental hygiene are invited to attend an open house every Friday afternoon followed by a seminar period.

PENNSYLVANIA

Society News.—Drs. Charles D. Ambrose, Ligonier, and Robert C. Johnston, New Kensington, addressed the Beaver County Medical Society, October 11, at Rochester, on "Endocrine Infantilism" and "Acute Intestinal Obstruction—Diagnosis and Treatment," respectively. Drs. Ethel F. Buchman and Lucy Etta B. Vaughn of the staff of the Allentown State Hospital addressed the Lehigh County Medical Society, October 9, on "Manic Depressive Psychosis" and "Involutional Melancholia," respectively. Dr. Sidney A. Chalfant, Pittsburgh, addressed the Erie County Medical Society, Erie, November 6, on diagnosis and treatment of uterine cancer.

Philadelphia

Mütter Lecture.—Dr. Charles H. Frazier, John Rhea Barton professor of surgery, University of Pennsylvania School of Medicine, delivered the Mütter Lecture of the College of Physicians of Philadelphia, December 5; his subject was "A Review, Clinical and Pathological, of Parapituitary Lesions."

Conference on Cancer Research.—The woman's auxiliary of the Lankenau Hospital Research Institute for the Promotion of Cancer Research sponsored its second annual conference, November 20, at the New Century Club. Dr. James B. Murphy of the Rockefeller Institute for Medical Research, New York, made an address on "Ideas and Ideals in Cancer Research"; Dr. Stanley P. Reimann, director of the Lankenau Hospital clinical laboratory, on "Current Events in Cancer Research," and Mrs. Lewis R. Dick, vice president of the auxiliary, "The 'Active Principle' in Cancer Research." In the afternoon a visit to the institute was scheduled, with an exhibition of apparatus, materials and methods and a motion picture showing behavior of living cells as special features.

Society News.—Speakers at a meeting of the Northern Medical Association of Philadelphia, November 19, were Drs. Abram H. Persky, on "The Tonsils and Their Role in Focal Infection"; Herman W. Ostrum, "Precordial Pain—The Etiology as Revealed by X-Ray Study," and Michael G. Wohl, "Renal and Extrarenal Coma." Dr. Meredith F. Campbell, New York, addressed the Philadelphia Urological Society, November 26, on "Bladder Outlet Obstruction in Infants and Children." At a meeting of the Eastern Pennsylvania chapter of the Society of American Bacteriologists, November 27, speakers included Drs. John A. Kolmer, on "A New Antigen for the Wassermann Test," and Ralph M. Tyson and Donald F. Lyle, "Infantile Diarrhea Due to B. Pyocyaneus."

RHODE ISLAND

Hospital News.—Dr. George Levene, Boston, gave an address at the State Hospital for Mental Diseases, Howard, on "Roentgenological Evidence of Cranial Dysplasias of Pituitary Origin." Dr. Joannes G. Dussier de Barenne, Sterling professor of physiology in the Yale University School of Medicine, New Haven, delivered an address, November 20, on "Recent Studies on Laminar Corticology."

TENNESSEE

University News.—Col. Fielding H. Garrison, librarian of the William H. Welch Memorial Library at Johns Hopkins University, addressed the faculty and students of Vanderbilt University School of Medicine, October 18, on "Life as an Occupational Disease."

Personal.—Dr. Cecil B. Tucker, Knoxville, has been appointed director of a recently organized health district made up of Anderson and Campbell counties. Dr. Fray O. Pearson, Alexandria, succeeded Dr. Tucker on the staff of the Knoxville health department. Another district has been organized to include Carter and Unicoi counties, with Dr. Russell B. Howard, Elizabethton, in charge and Dr. Bernard W. Patton, Memphis, as assistant in charge of Unicoi County, with headquarters in Erwin.

VIRGINIA

Professor Appointed.—Dr. Frederick B. Mandeville, director of the roentgenologic laboratory at Peralta Hospital, Oakland, Calif., for the past three years, has been appointed professor of roentgenology at the Medical College of Virginia, Richmond. He will also be full time roentgenologist to the hospitals operated by the college. Dr. Mandeville succeeds Dr. Daniel D. Talley Jr., who had served since the death of Dr. Alfred L. Gray, giving as much time as his private practice permitted.

University News.—Dr. Paul B. Barringer, University, is sponsoring a plan to place a marker on the home where Dr. Walter Reed lived while he was a student at the University of Virginia. The fourteenth postgraduate clinic at the University of Virginia Hospital was held November 16 in cooperation with the department of clinical education of the Medical Society of Virginia. Among the features were discussions of agranulocytosis by Dr. Henry B. Mulholland, laboratory diagnosis of anemia by Dr. William E. Bray and appendicitis in children by Dr. William H. Goodwin. Dr. Maximilian Ehrenstein, formerly lecturer in pharmacologic chemistry at the University of Berlin, has accepted a fellowship in physiology at the university for the current session to engage in investigations on the suprarenal glands.

GENERAL

Automobile Accidents Increase 16 Per Cent.—Approximately 28,400 persons were killed and 740,000 injured in automobile accidents during the first ten months of this year, according to figures compiled by the Travelers Insurance Company, Hartford, Conn. The number of deaths is an increase of 16 per cent over the number for the same period of last year, a fact which indicates that the full number for the year will reach an all-time record. The previous record was in 1931, when more than 33,000 were killed. Pedestrians were the victims in 48 per cent of the cases, as against 45 per cent for the whole of last year. August was the only month to show a decrease compared to the corresponding month of last year. Among states that reported through September, decreases occurred in Connecticut, Maine, New Hampshire and New Jersey. Available records show that there has been a gain of 24 per cent in the number of drivers who were declared intoxicated and a gain of more than 55 per cent among pedestrians declared intoxicated.

Society News.—Dr. Hermon Marshall Taylor, Jacksonville, Fla., was elected president of the Southern Medical Association at the annual meeting in San Antonio, Texas, November 13-16. Drs. Samuel Orr Black, Spartanburg, S. C., and John Manning Venable, San Antonio, were elected vice presidents. The next annual session will be held in St. Louis. At the annual meeting of the United States Live Stock Sanitary Association at the Hotel La Salle, Chicago, Dr. Paul B. Brooks, deputy health commissioner of New York, Albany, discussed milk-borne infections and Dr. Henry D. Chadwick, state health commissioner of Massachusetts, incidence of tuberculosis in school children. Dr. Hugh S. Cumming, surgeon general, U. S. Public Health Service, was unanimously reelected director general of the Pan-American Sanitary Office, and Dr. Justo F. Gonzalez, Uruguay, is secretary. Dr. Jorge Bejarano, Colombia, was elected organizing president for the tenth Pan-American Sanitary Conference, which will be held in Bogota, Colombia, in 1938. The 1935 conference of the American Federation of Organizations for the Hard of Hearing will be held in Cincinnati, June 2-6.

Fellowships in Physiology.—Four fellowships of \$250 each, to be awarded for the fifteenth International Physiological Congress in Leningrad-Moscow in 1935, are announced by the Federation of American Societies for Experimental Biology.

One fellowship will be awarded in each of the branches of biologic science represented by the four constituent societies of the federation; namely, the American Physiological Society, American Society of Biological Chemists, American Society for Pharmacology and Experimental Therapeutics and American Society for Experimental Pathology. Each candidate, who does not have to be a member of the federation, must be recommended by some member of the society representing the field of study or some other person familiar with the candidate's work. Candidates must be under 35 years of age and must not have attained professorial rank or its equivalent, and each must present with his application a draft of a meritorious paper to be presented at the congress. Applications must be made before Jan. 15, 1935, to the secretary of the society which includes the field of study. Secretaries are: for physiology, Dr. Frank C. Mann, Mayo Clinic, Rochester, Minn.; for biologic chemistry, Henry A. Mattill, Ph.D., State University of Iowa, Iowa City; for pharmacology and experimental therapeutics, Dr. Eugene M. K. Geiling, Johns Hopkins University School of Medicine, Baltimore, and for experimental pathology, Dr. Shields Warren, Palmer Memorial Hospital, Boston.

Look Out for Thomas Henry Robinson Jr.—The Division of Investigation of the U. S. Department of Justice reports that Thomas Henry Robinson Jr. is being sought in

connection with the kidnaping of Louisville, Ky., October 10, of Mrs. Alice Speed Stoll. This man has been receiving treatment for syphilis and is said to have "difficulty of a rheumatic nature with his feet." He has also been receiving treatment for "eye trouble." Robinson is 22 years old, is 6 feet tall, weighs about 149 pounds and is of slender build, with black hair, gray eyes and fair complexion. The photograph here reproduced was taken in June 1929. The Division of Investigation, U. S. Department of Justice, Washington, D. C., requests that any physician who comes into possession of any information concerning the whereabouts of

Thomas Henry Robinson Jr. notify it or the special agent in charge of the office of the division in the nearest large city in the state.

Change in Status of Licensure.—The state board of medical education and licensure of Pennsylvania at a meeting, October 18, took the following action:

License of Dr. Eugene Julius Hamborszky, Farrell, indefinitely suspended because of conviction on charges of narcotic violation and addiction.

License of Dr. A. F. P. Huston, Pittsburgh, which was suspended in June, restored with full rights to practice.

The Idaho Department of Law Enforcement reports the following:

Dr. Floyd A. Benjamin, Emmett, license suspended, August 14, for violation of the Harrison Narcotic Act.

The Maryland Board of Medical Examiners reports the following:

Dr. Benjamin H. Smart, North Beach, Md., license revoked, recently, because his license to practice in the District of Columbia had been revoked for a crime involving moral turpitude.

The California State Board of Medical Examiners announces the following:

Dr. Thomas Oliver Greig, Berkeley, license revoked, October 17, for violations of the terms of his probation imposed, Oct. 22, 1930, which prohibits his using or possessing alcohol.

Dr. Robert Vivian Baker, Avalon, license revoked, October 16, based on narcotic charges.

Dr. John R. U. Campbell, Dunsmuir, placed on probation for five years, October 16, during which time he shall not have nor apply for a narcotic permit or have narcotics in his possession.

Dr. Rudolph F. Rohling, Los Angeles, license restored, October 16; placed on probation for five years.

Dr. Roy F. Ruth, Los Angeles, license restored, October 17, placed on probation for five years without narcotic permit or privileges.

Dr. Arthur N. Nelson, Los Angeles, placed on five years' probation without narcotic permit or possession.

Dr. John Marshall Robinson, Los Angeles, placed on probation for five years, October 17, without narcotic privileges.

The Illinois State Department of Registration and Examination reports the following:

Dr. Jessie Abigail Shipley Traxler, Chicago, license revoked, November 3, for violation of the Harrison Narcotic Act; she is now in the federal industrial institution for women at Alderson, W. Va.

Geographic Distribution of Mortality.—A study of standardized death rates in individual states, recently published in the *Statistical Bulletin* of the Metropolitan Life Insurance Company, shows that North and South Dakota have the lowest mortality of any states, 7.9 and 7.6 per thousand, respectively. Next come a group of states with rates between 8 and 9, six in the Middle West: Nebraska, Kansas, Oklahoma, Minnesota, Iowa and Wisconsin, and three in the Northwest: Washington, Oregon and Idaho. The next range of death rates, from 9 to 10, is found in California, Wyoming, Montana, Utah in the West; Michigan, Indiana, Ohio, Kentucky, Missouri, Arkansas and Mississippi in the central part; Florida in the South, and Vermont, New Hampshire and Connecticut in the East. States with a rate from 10 to 11 include Maine, Massachusetts, Rhode Island, New York, Pennsylvania, New Jersey, Delaware, Maryland, Virginia, West Virginia, North and South Carolina, Georgia, Tennessee, Alabama, Louisiana and Illinois. The highest mortalities are found in Colorado and Nevada, with rates between 11 and 12, and in Arizona and New Mexico, more than 12. The high rates in these four states are probably due to the large proportion of Mexicans, among whom death rates are higher than among Americans, and to the influx of persons suffering from tuberculosis, the bulletin points out. In the Dakotas a favorable climate and the relatively safe and comfortable life on farms and in small towns combine to keep the inhabitants well, it was said. Reliable data were not available for Texas for the period considered in this study, 1929-1931.

Government Services

Changes in Public Health Service

Passed Asst. Surg. Frederick P. Burow, relieved at Ellis Island, N. Y., and assigned at Hamburg, Germany, in connection with the examination of aliens.

Passed Asst. Surg. Ivan W. Steele, relieved at Hamburg, and assigned at the American Consulate, Berlin, Germany.

Dr. Arthur B. Price, appointed and commissioned as assistant surgeon.

Asst. Surg. Henry L. Wollenweber, relieved at San Francisco and assigned at the National Institute of Health, Washington, D. C.

Warning About Cinchophen and Amidopyrine

The Food and Drug Administration has issued a warning to the public to be wary of cinchophen and amidopyrine, which are frequently used in remedies advertised for rheumatism and neuralgia. The statement pointed out that serious poisoning from these drugs develops insidiously, cinchophen causing degeneration of the liver cells and amidopyrine destruction of white blood cells. These drugs are not included in the list of those which the law requires manufacturers to declare on their labels, because cinchophen was unknown when the law was passed and the dangerous effects of amidopyrine had not been recognized. The administration urged buyers to look for declarations of the presence of the two drugs on labels or to write to Washington for information in case of doubt.

School for Children with Trachoma

A "trachoma school" has been opened on the Fort Apache Reservation in Arizona, in which about 300 children with trachoma will be placed under treatment. The school, which occupies a former boarding school, will be under the immediate direction of Dr. James C. Hancock, under the general supervision of Dr. Polk Richards, medical director of trachoma activities. Other such schools will be established later in areas where trachoma is a menace, according to an announcement by John Collier, commissioner of Indian Affairs.

CORRECTION

Carbon Tetrachloride as an Industrial Hazard.—In his article as printed in *THE JOURNAL*, September 29, page 962, Dr. Paul A. Davis wishes to make the following corrections: Under experimental data, 113,347.5 should read 113,311.47. In experiment 1, 126 should read 116. In experiment 2, 63 should read 58, 0.0076 should read 0.0079, and 76 should read 79. In experiment 4, 252 should read 232. In experiment 5, 0.1191 should read 0.1264, 1,008 should read 928, and 1,191 should read 1,264. In experiment 6, gram should read grain, 0.2382 should read 0.2370, and 1,890 should read 1,740. In experiment 8, 1134 pounds should read 2134 pounds, 0.234 should read 0.00435, and 0.37 should read 0.0069.

The Undiminishing Maternity Mortality

While the general death rate and the infantile death rate have been greatly reduced in recent years, the maternal death rate shows no diminution. The Ministry of Health has issued a circular to the local authorities saying that, in spite of what has been done in the past three years to improve and develop maternity services, the maternity mortality has not yet begun to fall. The minister recognizes that it could not be expected that the full effect of the measures which have been taken would so soon be reflected in the mortality statistics. At the same time he finds that there are still many areas in which the maternity service is neither complete nor satisfactory and that there are few, if any, in which there is not scope for further improvement. In all areas there is probably need for more intensive effort to educate women as to the importance of antepartum supervision and to persuade them to use the facilities provided for the purpose. The minister has on more than one occasion expressed the view that there is a clear case for development of the maternity service on urgent grounds of public health, and he considers that it would be true economy for each authority to do what is needed to provide a service that is both effective and comprehensive.

At a dinner of the British College of Obstetricians and Gynecologists, Mr. Baldwin, formerly prime minister, gave an assurance that the government wished the college well and had followed its work with interest. The college (which has only recently been established) hoped, he said, to do for obstetrics and gynecology what the College of Physicians was doing for medicine and the College of Surgeons for surgery. There was no doubt that, with all the work which had been done in regard to sanitation, housing and old age pensions, the whole question of child welfare and maternal mortality had come into the national picture in a way that it had never done before. The country did not realize that, while during the present century the general death rate had been reduced by about one third, tuberculosis had been reduced by an equal amount, and infant mortality by nearly one half, the maternal death rate was slightly increasing. It had been shown that half of the maternal deaths in Great Britain were preventable. That was a terrible indictment. It was extraordinary that the country had for so long taken these deaths, like accidents on the road, as a matter of course. They were in fact a reflection on the intelligence of the people and on humanity. There was also the suffering in later life from neglected childbirth. He had been told that, if the women received proper attention before and during childbirth and for a short time afterward, the number occupying women's wards in hospitals would be reduced by one half. Was there some factor to account for the high mortality which had hitherto escaped their vigilance? Could they not achieve closer working with the Medical Research Council? In reply, the chairman, Dr. J. S. Fairbairn, spoke of the work which the college had begun in conjunction with the National Birth Day Trust Fund in arranging a clinical investigation to alleviate the pains of childbirth among women attended only by midwives.

A meeting of more than 1,000 women was held at the Friends House, London, arranged by the Maternal Mortality Committee, whose report criticized the way in which local authorities were neglecting to make full use of the Maternity and Child Welfare Act and stated that the act was inadequate to deal with the present situation. Lady Denman, who presided,

read a telegram from Lord Horder suggesting that more attention should be paid to the question of the fitness of women to bear children and less to the competence of physicians and nurses. Mrs. Barton, of the Women's Cooperative Guild, moved a resolution stating that the conference was deeply impressed by the reports of malnutrition among married women, especially in areas of prolonged unemployment. Mrs. Frankenburg, a midwife, seconded the resolution but called attention to the fact that malnutrition was not the only cause of high maternal mortality, for statistics showed that the death rate was higher in the west end than in the east end of London. This important statement aroused a display of indignation from the socialistic audience bent on emphasizing malnutrition. Mrs. Frankenburg also caused indignation by saying that women needed education in what was the correct diet. There was too much preference for the tasty can of salmon compared with eggs and milk. Mrs. Sutherland, chief woman officer of the Labor Party, objected to these remarks and said that the can and the can opener were the only labor-saving devices within the reach of the working class woman. Lady Barrett, gynecologist of the London School of Medicine for Women, suggested that the best way to deal with malnutrition was to have a dining room for nursing mothers run in connection with antepartum clinics. The resolution was carried unanimously, as well as others to the effect that allowances should be paid in all maternity cases on the lines of national health insurance, that all local authorities should provide a complete gynecologic service, which would include advice on birth control, and that the minister of health and the British Medical Association should be asked to receive a deputation urging the wider provision of midwifery services and the fuller maintenance and development of child welfare and maternity services. With regard to malnutrition, there is, as the *Times* points out, the great difficulty of defining the condition. Sir F. Gowland Hopkins has said that the nutrition of every race is and has been imperfect.

The Change in Hospital Finance

Addressing the section of Odontology of the Birmingham Medical Institute, Prof. Leonard Gamgee described the great changes in hospital finance which have come about. Less than twenty years ago the voluntary hospitals were supported by endowments and subscriptions, and in some places, as in Birmingham, by workmen's contributions. But the great point was that no patient was ever charged a cent. Now almost every patient is charged a maintenance fee and the hospitals are supported in increasing degree by the cooperative contributions of the class from which the patients are drawn. The distinction between the voluntary and the municipal hospital is that the former is still not supported by the taxes. It is now realized that small contributions from wage earners and others can run hospitals, which are no longer primarily institutions for the treatment of the sick poor but for the treatment of subscribers to contributory systems, the majority of whom could not pay for treatment outside. Would physicians give the same honorary service to a cooperative insurance system as they were willing to give to a pure charity? Mr. Gamgee's answer was that he was glad that the time for making that decision did not come when he was doing active hospital work.

Control of the Sale of the Barbiturates

The tightening up of the regulations governing the sale of sleeping tablets has been strongly advocated by Sir William Willcox, the government toxicologist, and has been under the consideration of the official poisons board. He holds that the barbiturates should be obtainable only on a physician's prescription, that the pharmacist should retain the prescription, and that in no case should a fatal dose be supplied. But other

physicians think that the danger is exaggerated and do not agree with all these proposals. While the barbiturates, which are now obtainable from a pharmacist without any formality, should be supplied only on a physician's order, they hold it to be impracticable for a prescription to be obtained for every dose. Also, unless the prescription is endorsed "not to be repeated," it is the property of the patient. This raises the difficulty that the same prescription can be produced at any number of pharmacists' shops and an addict can thus obtain as much of the drug as he wants.

Children Taught to Wear Gas Masks

The possibility of another war is a common topic and among the horrors depicted are air attacks on cities, in which poison gas will play a part. It is stated that the war office is about to issue instructions to the civilian population as to their action in case of air attacks. Forty children have actually been taught how to wear gas masks in a mimic gas attack to which fireworks, a smoke screen made by smoke bombs, marked "gas zones," nurses and stretchers gave a touch of realism. The demonstration was held on Peckham Rye, one of London's open spaces. Those who took part in it were members of the British Red Cross Society and children of members. Commandant A. E. Skinner of the society showed the children, with the aid of a blackboard, how to wear the masks. Parents were invited to the demonstration, the idea of which was to train the children in discipline in the event of a real gas attack, and in the necessity and urgency of respiration. Oxygen cylinders were available.

Subsequently the British Red Cross Society repudiated responsibility for the demonstration. It understood that the press wanted to see how voluntary aid detachments were trained and were willing for this to take place. But the society gave no authority whatever for children to take part in a mimic gas attack. The society has nothing whatever to do with the training of children. It is contrary to its policy and this demonstration had nothing whatever to do with the society.

A Bill to Limit the Number of Medical Students

Prof. George Portmann of Bordeaux has just submitted a bill, in his capacity as senator, which will be discussed this fall before the senate and the house of representatives. The proposed law will greatly limit the number of medical students, which has increased from 8,182 in 1929 to 10,338 in 1933. The number of graduates in 1930 was 1,076 and in 1933 it rose to 1,397. The ratio of the number of physicians in France to the population is 1 to 1,645. In Paris alone there is one physician to 630 civilians.

Germany has recently decided to limit the number of students in the universities to 15,000 instead of 25,000 as in 1933. This would appear to be too radical a limitation in the case of France.

Efforts have already been made by the various French medical schools to cut down the number of students. Instead of oral examinations, which are often unfair to the student, a system of written examinations is being introduced. So far it has been limited to the first two of the six years medical course. Only recently the number of years required has been changed from five to six. Many complaints have been received as to the laxity of the method of examinations, but an effort is being made to meet this just criticism. Professor Portmann believes that all these measures are inadequate, and, in view especially of present economic conditions, some corrective measures are imperative.

At the present time a medical student must have passed examinations equivalent to at least the first two years of the college courses given in the majority of the American universities. The Bachelor of Arts degree requires only two years of study at the French lycées or colleges, but the number of required courses is more than equivalent to the first two years of the American college courses. This degree is required before a student can enter the medical school. After entering, there is an obligatory preliminary year devoted to physics, biology and chemistry. These courses are not given at the medical school proper.

The new law proposes to have a committee composed of the heads of the departments of war, navy, colonies and education. These shall determine the number of medical students needed each year. If they decide, for example, that the number should be 1,000 for a given year, the 1,500 students receiving the best examination averages at the end of the preliminary medical year (physics, biology and chemistry courses) shall be permitted to enter the first year of the medical course. The 1,000 students (of the original 1,500) receiving the highest averages in the preliminary (basic sciences) year shall be permitted to enter the first medical school year.

In 1900 there were 16,815 physicians in France itself, and in 1928 this number had risen to 27,000, whereas there was an increase in population of only two million. The University of Paris medical school alone has more than 4,000 students, all under the supervision of a single faculty.

Is Social Insurance a Success?

In the November 14 issue of the *Concours médical*, a very instructive article by Dr. P. Dally gives some statistical data that will be of value in the evaluation of proposed legislation in the United States to establish sickness insurance under state or national supervision. When Bismarck in 1886 proposed such a law in Germany, his object was to neutralize the rapidly growing Socialist party, which demanded higher wages rather than compensation for illness. Laws of the latter kind have never been popular with the working classes, and even less so with the medical profession. According to Dally, such legislation was due to political considerations that aimed primarily to distribute public funds to the masses. The care of the sick was a secondary consideration. None of these laws had as their object public health in the larger sense; that is, no efforts were made in the direction of preventive measures. This seems rather paradoxical when one recalls that such efforts would have only resulted in a decrease in the amount of money needed to carry out the laws and thus, in the final analysis, have lightened the burden of those who were contributors and beneficiaries of the fund. These laws, especially in countries like Germany and Austria, where they were first employed, are still in an experimental stage, as evidenced by the constant changes that are being made, as the result of the demands of the employer and the employee.

A vital error lies in the fact that these laws attempt to solve an intangible question of morals such as the reciprocal relation of patient and physician. The insured worker in many instances tries to get back the money he has paid by malingering, by exaggeration of the time needed to recuperate and by dissatisfaction with the percentage of his invalidity which has been decided on by the medical examiners. Kirschner, a German surgeon of international reputation, says "Our country is like a huge hospital, a community of invalids, where every individual tries to grab as much as possible out of the big indemnity bag into which he pours his contributions." One out of every seven persons is a beneficiary of the sick relief funds, in Germany. There have been as many officials to administer these funds as beneficiaries in Germany. This is already the complaint in France, even though the law is only four years

old. In countries where insurance against illness was optional, it has become obligatory. Where formerly there was only a patient and a physician, the decisions of the latter are subject to supervision by a medical government employee. There is constant friction in countries where there is obligatory sickness insurance. In Austria the law has been modified twenty-eight times since its passage in 1887.

This conflict will cease perhaps, some day, when the national insurance agencies have at their disposal a corps of medical government officials who devote their entire time to the care of the assured. There will be no further conflict, because there will no longer exist a medical profession in the present interpretation of the words. A better method, perhaps, of utilization of the large funds of these state insurance departments would be to create large diagnostic centers and hospitals, which would permit better care to be given to the worker. Some efforts are being made in this direction.

There are few countries in which the medical profession has neither been consulted in the passage of legislation for sickness insurance, nor even consulted from time to time in the management of the departments. This is certainly true of France.

Neither the assured nor the medical profession is satisfied with social insurance laws. Among nineteen countries of Europe this is the opinion in all except Bulgaria, Denmark, France and Holland. In Yugoslavia the insured is satisfied, but not the medical profession. Some very instructive tables accompany the article of Dally, from which some data are as follows:

Free choice of physicians: Yes in Bulgaria, France, Great Britain, Holland, Norway, Sweden and Switzerland. No in Germany, Esthonia, Hungary, Latvia, Poland, Czechoslovakia, Yugoslavia and the city of Vienna.

Who is obliged to be insured? In Germany, every worker earning less than \$900, in France all less than \$1,100, in Great Britain all less than \$1,200 and also all manual workers. In Germany, this means nearly one third, in France about one fifth and in Great Britain about two fifths of the total number of inhabitants.

If those who have charge of social insurance would not neglect to utilize the vast funds at their disposal in greater efforts to prevent disease, much good could be accomplished, is the conclusion of Dr. Dally.

VIENNA

(From Our Regular Correspondent)

Oct. 23, 1934.

The Tenth Convention of Physicians of the Alpine Region

The tenth annual meeting of physicians in the region of the Alps was held in Graz, October 8-10. More than 400 of the leading physicians from Austria, Switzerland and Italy attended. Under the chairmanship of Prof. Dr. Wittek of Graz a memorial tablet in honor of the deceased surgeon Prof. Hacker was unveiled. The first subject discussed was the problem of thrombosis and embolism. Because of the illness of Prof. Dr. Maresch, chief pathologist of the Vienna General Hospital, the paper was read by his assistant Dr. Feller. He emphasized that the nature of this dangerous disorder has not yet been fully explained. The assertion that this condition has enormously increased was investigated on the basis of 70,000 post-mortem reports. The assertion proved to be greatly exaggerated. "Compared to the prewar period, only a slight increase could be ascertained." Professor Maresch assumes that this increase is caused by the "over aging" of the population; that is, the relative and absolute increase in the higher age groups as the result of the decrease in the birth rate and an increase in the longevity. He also emphasized the relation of the dis-

order to meteorological factors. In cooperation with the director of the Central Meteorological Institute in Vienna, it could be established by exact analysis of all the characteristics of the weather that there is a connection between the incidence of the disorder and abnormal temperatures and barometric conditions, particularly in regions with damp and hot sea winds.

The treatment and clinical aspects of embolism and thrombosis was discussed by the Viennese clinicians Eppinger as internist and Ranzi as surgeon. The first speaker discussed the etiology. The development is especially likely during prolonged rest in bed, after operations, bone fractures and deliveries. All these conditions involve injuries of the tissues, which produce changes in the blood vessels, which in turn favor the development of thrombi. For this reason, attempts should be made to accelerate the circulation. Great stress has been placed in recent years also on the treatment that employs exercises and aims to shorten the patient's rest in bed as much as possible. Massage of the extremities has been recommended particularly after operations. The surgical aspects were discussed by Professor Ranzi and Professor Denk, and especial attention was called to the significance of previous operations. Getting out of bed early after operations is to be recommended whenever possible, particularly in patients over 45 years of age.

After that, the hygiene of large cities was discussed. Dr. Gegenbauer, chief of the health department of the city of Vienna, reported on the sources of infection of abdominal typhoid.

Prof. Dr. Hamburger of Vienna spoke on the significance of the formation of habits in clinical pathology. He showed that on the basis of certain habits that are formed during childhood (tic, vomiting, morbid sleepiness) there develop certain disorders, in the treatment of which psychic factors and suggestion play an important part.

Dr. Kauders of Baden, near Vienna, discussed "light diet," which is indicated in disturbances of the digestive tract, in renal diseases, in circulatory disturbances and in hormone disorders. It is possible that a light diet which is deficient in vitamins may lead to the development of scurvy-like conditions; also a hypersensitivity may develop to some of the constituents of the light diet (milk, eggs). The patient may develop urticaria, pruritus, transitory edema and even angina pectoris and gastric hemorrhage. Every restricted diet, whether a vegetable diet, raw diet, Gerson diet, salt-free diet (Noorden) or fat diet, requires careful adaptation to the individual case.

The causes and the treatment of anemia were discussed by Dr. Naegeli of Zurich. Modern diagnostic methods make possible a precise differential diagnosis and accordingly the prescription of iron and arsenic, of cod liver oil or of liver preparations; and in acute conditions blood transfusions.

Professor Schinz of Zurich, the chairman of the convention of roentgenologists in Switzerland, described his research on the roentgenologic diagnosis of diseases of the vertebral column. Roentgenoscopy reveals entirely new aspects in the case of tumors and of tuberculosis of the vertebrae. Accordingly, the treatment has made considerable progress in these conditions.

"Glandular fever," which in children was first described by Pfeiffer, was discussed by Professor Jagić of Vienna. In recent years this disorder has been observed also quite frequently in adults. The patients developed fever, also swelling of the glands in the region of the lower jaw, of the neck and of the axilla, splenic tumor and various changes in the blood picture somewhat like those in genuine forms of leukemia. The prognosis is generally favorable.

Professor Berger and Dr. Grill of Graz spoke on the artificial production of pernicious anemia in animals by prolonged poisoning with carbon monoxide gas. In a human case, in which the cause was recognized, cure was effected by the removal of the cause (poisoning with carbon monoxide of several years' duration) and by liver diet.

Prof. Dr. Hiess of Klagenfurt spoke on prophylaxis during pregnancy. He stressed the necessity of at least two examinations of the pregnant women before delivery. Tuberculosis and even malignant and benign tumors do not exclude a normal delivery, provided the prophylaxis has been adequate. Especial attention should be given to the "old primiparas," but the author has seen normal deliveries in women who were nearly 50 years old.

The calculation of the day of delivery was elucidated by docent Dr. Kraul. Nine months plus seven days after the last menstruation, the well known formula of Naegeli was taken as the basis in 22,000 cases within the last eight years in the First Women's Clinic of Vienna. It was found that this formula gave only an average duration. The opinion about "past term" infants, that is, the dependence of weight and length of the newborn on the duration of the pregnancy, could not be corroborated. The deviations from the calculated date of birth are due to differences in the constitution. The average duration of 266 days can be subject to considerable changes, between 258 and 297 days.

Organization of the Medical Profession of Austria on the Basis of the New Organization of the State

Since the political revolution in Austria in February 1934, the entire direction and constitution of the state have undergone fundamental changes. Austria is ruled on the basis of "estates" (corporate bodies) that correspond somewhat to the medieval crafts or guilds. Persons connected with sanitation in the future will be organized and united in two guilds, the "health guild" and the "physician's guild," in spite of the fact that certain formal connections may exist between the two as far as physicians are concerned. The "health guild" includes all private physicians, veterinarians, midwives and the personnel assisting the physicians. Excluded are all persons who are in public service, since these are already incorporated in the "official's guild." The representatives of this "health guild," who are to function in the councils (called Culture Council), in order to look out for the interests of this guild in legislation and in other governmental activities, are appointed (not elected) by the minister for social organization. The "physician's guild" itself is a professional organization in the "health guild." The organ of this physician's guild is the "physician's chamber" for professional and economic concerns. These chambers are divided into two sections (a) for the court of honor (medical ethics) and (b) for economic problems. The regional institutions of the physicians remain in existence as such but the state or provincial representations are to be given a unified "fuhrung" (leader). This "leader" is appointed and he is assisted by a council, the members of which at first are likewise appointed. On the whole, the principle of election, which formerly dominated everywhere, has been completely done away with, authority rules. However, it should be added here that all these regulations are only a transition to a "limited democracy." A (provisional) physician's "federal economic council" is to be created, the members of which are to be appointed by the government. The latter is to select men who appear suitable, but they must belong to the "fatherland front," which is considered the bearer of the political power in Austria. All former political parties have been dissolved voluntarily or by law; almost every one in Austria who does not wish to give the appearance of being an enemy of the state must be a member of the "fatherland front," physician's likewise. In this manner the new physician's organization is clearly political.

The new organization has not been completely accepted as yet. It is criticized by the medical profession and by others, by persons who are not at all unfriendly toward the new aims but who only wish to correct defects. Medical circles are under the impression that the official character of the physician's

chamber will be a hindrance in the representation of purely medical interests. Formerly the economic organization was energetically active in such matters, and because of its independence from the government it was rather strong and quite successful in its activity for the physicians. Since a reform of the *krankenkassen* and of the social insurance system is to be expected in the near future, and also a new law for the medical profession, the fact that many experienced and competent members of the old physician's chamber and medical organizations have not been reappointed has created a most disagreeable surprise. It is feared that the efforts made by physicians for many years to improve their condition may now fail completely. At any rate, many physicians are in grave doubt about the future. Everywhere the tendency is noticeable to pension the older men and to force the younger men who formerly had different political convictions than the now ruling elements out of their positions without pensions. This applies particularly to former social democrats and to national socialists but also to nonpolitical Jews, who in this manner could be forced into a hidden "numerus clausus."

BUENOS AIRES

(From Our Regular Correspondent)

Oct. 20, 1934.

Medical Congresses in Argentina

The Fifth National Congress of Medicine of Argentina was held in Rosario, September 2-7, with a large attendance. The official topic was "Amebiasis," which was presented by Drs. Castex, Staffieri and Franchini (clinical aspects), Marotta (surgery) and Greenway and Mazza (parasitology), as official speakers. Papers were read by Drs. T. M. Rivera on filtrable viruses, Brauer on collapsotherapy, Fonesca on mycotic allergy, Binet on the suprarenals and the metabolism of sulphur, and Lipschütz on the gonadotropic action of the hypophysis. Members of the sections of histology, pathologic anatomy, physiology and biochemistry, hygiene, legal medicine, medical clinics, pediatrics, surgery, ophthalmology, urology, otorhinolaryngology, pharmacy, odontology and naval and military medicine, convened in several meetings. Dr. B. A. Houssay spoke on functions of the anterior lobe of the hypophysis and Dr. Cíbils Aguirre on antidiphtheritic vaccination. The next national congress will meet in Córdoba in 1938.

The first Congress on Medical Economics, organized by the Colegio Médico, a medical society of Buenos Aires, with the cooperation of similar medical societies of Argentina, was held, June 24-30, in Buenos Aires. Important problems of collective medical practice were discussed. The members resolved to have a fixed tariff of fees, in relation to the economic conditions of patients, who were classified as "poor," "justified to have a 60 per cent reduction in the schedule," and "able to pay the whole fee assigned in the schedule." They also resolved to have the City Hospital and similar institutions as centers for free medical care. There were various general motions, such as on the preparation of a national sanitary code. The existence of sanatoriums belonging to medical cooperative and medical mutual societies was approved. The members stated that the medical profession in Argentina is overcrowded and advised the limitation of the number of students to medical schools in relation to the health demands of the country, as well as the selection of candidates, according to their preparation and ethical background. The suppression of treaties of reciprocity with various countries was advised as an aim of securing practice for Argentine physicians, those graduated from Argentine schools as well as those returning home with diplomas from accredited schools in other countries.

The annual Congress of Surgery will meet October 21. The ninth Pan-American Sanitary Conference, organized by a committee under the chairmanship of Dr. G. Araoz Alfaro, with

Drs. M. Sussini and M. Obarrio as vice presidents and Drs. A. Zwanck and A. Sordelli, as secretaries, will meet November 12-22.

Lectures by Foreign Professors

Well known foreign professors were presented to the Congress of Medicine recently held in Rosario. During their stay in Argentina the following delivered lectures: Prof. Léon Binet, teacher of physiology of the Faculty of Medicine of Paris, a course of twelve lectures on physiology of the lung, oxygenotherapy, intestinal occlusion, hyperthermia, and some other topics. Prof. T. M. Rivers of the Rockefeller Institute on filtrable viruses; his lectures were delivered in Spanish. Prof. Bastos Ansart of Madrid, on cerebral surgery. Prof. L. Brauer of Hamburg, on physiology of exercise, aeronautic medicine and collapsotherapy; his lectures were delivered in Spanish. Professor Franchini of Modena, on amebiasis. Professor Bottazzi of Naples, on Leonardo da Vinci, factors of alimentation, and muscular tonus. Prof. O. da Fonseca of Rio de Janeiro, on parasitology. Professor Lichtenberg of Berlin, on urinary pathology and pyelography. Professor Munk of Berlin, on vascular and renal pathology.

Mottled Enamel

Drs. Goldenberg in 1917 and Bergara in 1927 reported the results of their experiments on the action of fluorine. Dr. Chaneles in 1930 reported results of a thorough study of the action of fluorine on the teeth of rats. Research has been focused this year on the geographic distribution of mottled enamel in relation to the contents of fluorine in drinking water in Argentina. Dr. R. Erasquin reviewed and completed a map prepared by Dr. Damon, showing the geographic distribution of the dental condition. Dr. J. M. Muñoz performed an analysis of drinking waters in the zones in which the inhabitants have mottled enamel. He found a content of 2.4 mg. of fluorine per thousand cubic centimeters in drinking waters in those zones, by working with Casares' method. Dr. Trelles, however, made some objections on the exactness of the method (*Semana médica*, October 4).

Anaerobic Actinomycetes

Negróni has verified the failure to obtain cultures of either Actinomycetes or Actinobacilli in aerobic mediums in many cases of actinomycosis with clubs. He prepared cultures in anaerobic mediums, in agar and dextrose, and succeeded, in seven cases out of ten, in obtaining cultures of *Streptothrix israeli*, to which he gives the designation *Proactinomycetes israeli*, following the classification of Actinomycetaceae given by Jensen in 1931. The results of his work seem to indicate that mycetoma may be caused by Actinomycetes, by Actinobacilli or by Proactinomycetes.

Tuberculosis and Erythema Nodosum

Dr. A. Arenas recently reported before the Sociedad de Biología the results of his experiments on erythema nodosum. The author was able to obtain visible tubercle bacilli, after the first series of inoculations subcutaneously and by means of the lymph nodes, in only one case out of seven cases of erythema nodosum. Acid-fast bacilli of an increasing virulence appeared, however, after successive inoculations from animal to animal, in the material of five out of that of the seven cases.

Deaths

Dr. J. M. Escalier, formerly head of the Rivadavia and Durand hospitals, and ex-president of the Asociación Médica Argentina, born in Bolivia, died August 15 at the age of 70. —Dr. J. M. Zubizarreta, formerly head of the pediatric department of the Hospital de Niños la Casa de Expósitos, and ex-director of public welfare of the federal capital, died October 13. —Dr. Ernesto Romagosa, professor of surgical clinics of the Faculty of Medicine of Córdoba, ex-dean of the faculty and ex-rector of the university, died recently.

Marriages

CECIL STUART EUGENE TOUZEL, Fort Worth, Texas, to Miss Gwendolen Williamson Cole at Point Fortune, Que., Canada, August 23.

LEONARD KIRK MCMURTRY, Evansville, Ind., to Miss Ruby Ray Douglas of Princeton at Henderson, Ky., September 15.

JASPER STEWART HUNT, Charlotte, N. C., to Miss Eleanor Louise Bomar of Spartanburg, S. C., October 6.

LUTHER C. MITCHELL, Sandersville, Ga., to Miss Lamartine Christian of Madison in Augusta, September 30.

JOHN W. PYLES to Miss Erica Tanner, both of New Martinsville, W. Va., in Pittsburgh, October 12.

EDWARD VICTOR DENNEEN, New York, to Miss Julia Theresa Corcoran of North Bay, N. Y., October 17.

JOSEPH D. CULBERTSON, Norton, Va., to Miss Flossie Bradle of Eureka, Ill., at Pekin, Ill., October 13.

BEVERLEY EUGENE SMITH, Baltimore, to Miss Mary Wini-fred Davis of Oxford, Miss., October 1.

FELIPE ANDRES MARTINEZ to Miss Marguerite Gertrude Kurdle, both of Baltimore, August 8.

SIDNEY S. BERKOWITZ, New York, to Miss Miriam H. Rosenfeld of Philadelphia, October 5.

LOREN K. MEREDITH to Miss Elizabeth Ruth Brinton, both of Des Moines, Iowa, October 12.

FRANCIS M. CONWAY, Brooklyn, to Miss Jean Mayer of Montclair, N. J., September 12.

LEO E. GIBSON, Syracuse, N. Y., to Miss Pauline Remington of Potsdam, N. Y., October 3.

SEWELL B. COULSON, Waldron, Ind., to Miss Helen Jackson at Indianapolis, September 9.

RAY S. CRIST, Port Townsend, Wash., to Miss Josephine E. Reasor of Seattle, August 25.

WILLIAM F. BELL, Kalvesta, Kan., to Miss Winefred Beeman at St. Louis, September 12.

CARL H. SENN, Williamsport, Pa., to Mrs. Helen Hayes of Philadelphia, August 20.

WEBSTER K. ROSS to Miss Vina Conley, both of La Grande, Ore., August 19.

JAMES R. HART to Miss Myra Disterdiek, both of Erie, Pa., August 22.

JOHN J. MRAZ to Miss Jannette Harkins, both of Erie, Pa., August 29.

Deaths

August Frederick Jonas ♂ Omaha; Bennett College of Eclectic Medicine and Surgery, Chicago, 1877; Ludwig-Maximilians-Universität Medizinische Fakultät, Munich, Bavaria, Germany, 1884; in 1901 third Vice President, in 1906 and in 1911 member of the House of Delegates, and in 1912-1913 Chairman of the Section on Surgery of the American Medical Association; professor of surgery, emeritus, University of Nebraska College of Medicine; member of the American Surgical Association and the Western Surgical Association; fellow of the American College of Surgeons; served during the World War; at various times on the staffs of the Nebraska Methodist and the Douglas County hospitals; aged 76; died, November 13, of cerebral hemorrhage.

Herbert Melville Little, Montreal, Que., Canada; McGill University Faculty of Medicine, Montreal, 1901; professor of obstetrics and gynecology at his alma mater; member and formerly vice president of the American Association of Obstetricians, Gynecologists and Abdominal Surgeons; member of the American Gynecological Society; fellow of the American College of Surgeons; gynecologist to the Montreal General Hospital; gynecologist and obstetrician to the Royal Victoria Hospital, formerly known as the Montreal Maternity Hospital of which he was superintendent; on the editorial board of the *Canadian Medical Association Journal*; aged 56; died, October 11.

Creswell T. Pigot ♂ Roundup, Mont.; Western University Faculty of Medicine, London, Ont., Canada, 1900; member of the House of Delegates of the American Medical Association, 1922-1934; past president of the Medical Association of Montana; secretary of the Musselshell County Medical Society; served during the World War; city and county health officer;

fellow of the American College of Surgeons; on the staff of the Musselshell Valley Hospital; aged 55; died, October 12, of pneumonia.

George Forrest Martin ♂ Lowell, Mass.; New York Homeopathic Medical College and Hospital, 1890; fellow of the American College of Surgeons; member of the school committee, 1894-1895; in 1909 member and in 1910 chairman of the board of health of Lowell; senior surgeon to the Lowell General Hospital; for many years chairman of the board of trustees of the State Infirmary, Tewksbury; aged 71; died, November 4, of coronary thrombosis.

Stanley Stillman, San Francisco; Cooper Medical College, San Francisco, 1889; member of the California Medical Association, the American Surgical Association and the Pacific Coast Surgical Association; fellow of the American College of Surgeons; professor of surgery emeritus, Stanford University School of Medicine; aged 73; consulting surgeon to the Lane Hospital, where he died, October 15, of pneumonia.

William Scott Campbell, Chicago; Rush Medical College, Chicago, 1885; member of the Illinois State Medical Society; past president of the Tippecanoe County (Ind.) Medical Society; for many years health commissioner of Tippecanoe County, Ind.; aged 77; died suddenly, November 3, at his home in Oak Park, Ill., of angina pectoris.

Stephen August Stadler, Kansas City, Mo.; St. Louis University School of Medicine, 1917; member of the Missouri State Medical Association; served during the World War; on the staffs of the Kansas City General and St. Joseph hospitals; aged 44; died, November 1, of hemorrhage from esophageal varices and cirrhosis of the liver.

Arthur Freeman ♂ Surg., Lieut. Commander, U. S. Navy, retired, Washington, D. C.; Vanderbilt University School of Medicine, Nashville, Tenn., 1914; entered the Navy in 1917 and retired in 1932 for incapacity resulting from an incident of service; aged 48; died, October 20, in the U. S. Naval Hospital, of esophageal abscess.

Paul Ewing McDonnold ♂ P. A. S., Lieut. Commander, U. S. Navy, retired, Riverside, Calif.; Columbian University Medical Department, Washington, D. C., 1898; entered the navy in 1901 and retired in 1910 for incapacity resulting from an incident of service; aged 61; died, September 20, of chronic rheumatic endocarditis.

Arthur C. Merriam, Washington, D. C.; Columbian University Medical Department, Washington, 1889; served during the World War; formerly connected with the U. S. Public Health Service; aged 68; died of drowning, coronary thrombosis and embolus when he fell from a yacht in the Anacosta River, October 11.

James Bernard O'Neill, Portland, Maine; Harvard University Medical School, Boston, 1887; member of the Maine Medical Association; veteran of the Spanish-American War; formerly on the staff of the Maine Eye and Ear Infirmary; aged 74; died, October 20, of heart disease and arteriosclerosis.

Lester F. Newbern, Monroe, Mich.; State University of Iowa College of Medicine, Iowa City, 1908; member of the Michigan State Medical Society; past president of the Monroe County Medical Society; on the staff of the Monroe Hospital; aged 50; died, November 11, of heart disease.

Richard Aloysius McGillicuddy ♂ Turners Falls, Mass.; Baltimore Medical College, 1903; for many years member and chairman of the school board; on the staff of the Farren Memorial Hospital, Montague City; aged 55; died, November 4, of chronic valvular heart disease.

John Victor Lynn, Ridgefield, N. J.; Hahnemann Medical College and Hospital, Chicago, 1905; member of the Medical Society of New Jersey; served during the World War; aged 58; on the staff of the Holy Name Hospital, Teaneck, where he died, November 13, of heart disease.

Eugene A. Harris ♂ Navasota, Texas; Tulane University of Louisiana Medical Department, New Orleans, 1890; president of the Grimes County Medical Society; on the staff of the Brazos Valley Sanitarium; aged 65; died suddenly, October 26, of heart disease.

William T. Morgan, Braddock, Pa.; University of Maryland School of Medicine, Baltimore, 1884; for many years president and on the staff of the Braddock General Hospital; aged 76; died, October 9, at his home in Swissvale, of carcinoma of the stomach.

Burgett Woodcock, Greeley, Colo.; Medical College of Alabama, Mobile, 1896; member of the Colorado State Medical Society; served during the World War; formerly on the staff of the Greeley Hospital; aged 59; died, October 19, of heart disease.

Joseph Wright Allen, Monongahela, Pa.; Cleveland Homeopathic Medical College, 1907; member of the Medical Society of the State of Pennsylvania; on the staff of the Memorial Hospital; aged 52; died, August 11, of cerebral hemorrhage.

Leigh Hubbard Womble Jr., Mitchell, Neb.; University of Nebraska College of Medicine, Omaha, 1933; aged 24; died, October 18, of a gunshot wound received in the premature discharge of a shotgun in the hands of a hunting companion.

Julian Raymond Blackman, Salt Lake City, Utah; Johns Hopkins University School of Medicine, Baltimore, 1906; served during the World War; aged 56; died, November 11, in the Veterans' Administration Hospital, of angina pectoris.

Joseph Jordan Robertson @ Kingsville, Texas; University of Texas School of Medicine, Galveston, 1913; served during the World War; aged 48; on the staff of the Kleberg County Hospital, where he died, October 5, of nontropical sprue.

Howard F. Hansell, Philadelphia; Jefferson Medical College of Philadelphia, 1879; emeritus professor of ophthalmology at his alma mater; formerly ophthalmologist to the Philadelphia Hospital; aged 78; died, November 5, of heart disease.

George Leslie Lynch, Amador City, Calif.; College of Physicians and Surgeons of San Francisco, 1906; for many years county health officer; aged 60; died, October 6, in the Sutter Hospital, Sacramento, of streptococcal septicemia.

Samuel L. Friduss @ Chicago; College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1897; on the staff of the Englewood Hospital; aged 64; died, November 10, of carcinoma of the bladder.

Thomas W. Moorhead @ Terre Haute, Ind.; College of Physicians and Surgeons of Indiana, Indianapolis, 1876; aged 78; formerly on the staff of St. Anthony's Hospital, where he died, November 8, of carcinoma of the rectum.

Albert Ward Preston @ Middletown, N. Y.; Columbia University College of Physicians and Surgeons, 1896; on the staff of the Elizabeth A. Horton Memorial Hospital; aged 65; died, October 12, of coronary thrombosis.

James A. Clark @ Chicago; Chicago Medical College, 1885; aged 73; formerly on the staff of St. Anthony's Hospital; on the staff of the West Side Hospital, where he died, September 29, of uremia, following a prostatectomy.

William I. Timmer, Cicero, Ill.; Chicago College of Medicine and Surgery, 1911; member of the Illinois State Medical Society; on the staff of the West Suburban Hospital; aged 54; died, November 14, of heart disease.

Geoffrey Orlando Tunison, Oxford, N. J.; Jefferson Medical College of Philadelphia, 1885; member of the Medical Society of New Jersey; aged 71; died, November 4, of septicemia, prostatitis and arteriosclerosis.

William Ralph Eddleman, Anna, Ill.; University of Tennessee College of Medicine, Memphis, 1912; aged 46; died, October 17, as the result of injuries received in an automobile accident and of cirrhosis of the liver.

Edward Walker Blackburn, Ozark, Ark.; Vanderbilt University School of Medicine, Nashville, Tenn., 1900; member of the Arkansas Medical Society; also a druggist; aged 59; died, October 31, of cerebral hemorrhage.

William H. Pauley, St. Louis; Marion-Sims College of Medicine, St. Louis, 1896; member of the Missouri State Medical Association; aged 60; died, October 21, in the City Hospital, of cerebral hemorrhage.

Charles Henry Pope @ St. Louis; Barnes Medical College, St. Louis, 1904; served during the Spanish-American and World wars; aged 58; was found dead in his automobile, November 3, of heart disease.

Fred Fernando De Vore, Toledo, Ohio; Medical College of Ohio, Cincinnati, 1900; served during the World War; for many years county health officer; aged 55; died suddenly, October 21, of heart disease.

James Sigel Wiltshire, Londonderry, Ohio; Starling Medical College, Columbus, 1897; member of the Ohio State Medical Association; aged 74; died, October 30, of chronic nephritis and prostatitis.

James Oliver Mohn, Gowen City, Pa.; Jefferson Medical College of Philadelphia, 1894; member of the Medical Society of the State of Pennsylvania; aged 66; died suddenly, October 2, of angina pectoris.

Joel Sperans, Los Angeles; University of Buffalo School of Medicine, 1905; aged 70; died, September 6, in the Cedars of Lebanon Hospital, of uremia, chronic nephritis and hypertrophic prostatitis.

Albert S. Munson, DeLand, Fla.; Bennett College of Eclectic Medicine and Surgery, Chicago, 1873; member of the Florida Medical Association; aged 83; died, October 22, of bronchopneumonia.

Edwin K. Wilson, Romney, W. Va.; Jefferson Medical College of Philadelphia, 1877; member of the West Virginia State Medical Association; aged 80; died, October 14, of cardiac insufficiency.

James Edward Johnson, Grantsburg, Wis.; Marquette University School of Medicine, Milwaukee, 1914; on the staff of the Community Hospital; aged 53; died, November 4, of heart disease.

John Brown Harris, Nashville, Tenn.; Vanderbilt University School of Medicine, Nashville, 1901; aged 84; died, November 5, of uremia and fracture of the right femur as the result of a fall.

James Lafayette Ledgerwood, Tishomingo, Okla.; Vanderbilt University School of Medicine, Nashville, Tenn., 1886; aged 73; died, July 27, in the Hardy Hospital, Ardmore, of uremia.

William F. Schwartz, Baltimore; University of Maryland School of Medicine, Baltimore, 1907; aged 49; died, October 25, in St. Joseph's Hospital, following an operation for gastric ulcer.

David John @ Yonkers, N. Y.; L.R.C.P., London, and M.R.C.S., England, 1882; for many years on the staff of St. John's Hospital; aged 76; died, November 10, of heart disease.

Francis Marion Granger, Russell, Ohio; Medical College of Ohio, Cincinnati, 1873; member of the Ohio State Medical Association; aged 87; died, November 14, of heart disease.

George P. Gerichten, San Francisco; California Medical College, Oakland, 1901; aged 59; died, September 6, in the Franklin Hospital, of acute atrophy of the liver.

Fred E. Tuttle @ Cattaraugus, N. Y.; University of Buffalo School of Medicine, 1880; aged 77; died, July 10, of bronchopneumonia and carcinoma of the prostate.

Othello C. Scarborough, Joplin, Mo.; University of Louisiana Medical Department, New Orleans, 1874; aged 84; died, October 11, of chronic valvular heart disease.

Stephan Stephanson, The Pas, Manit., Canada; Manitoba Medical College, Winnipeg, 1912; aged 48; died, September 18, in Winnipeg, of acute appendicitis.

Henry Franklin McCool, Evansville, Ind.; Miami Medical College, Cincinnati, 1887; aged 71; died, October 24, in St. Mary's Hospital, of heart disease.

Charles Frank Rotter @ St. Louis; Marion-Sims College of Medicine, St. Louis, 1896; aged 73; died, October 7, of chronic myocarditis and nephritis.

Thomas Franklin Oates @ Mexia, Texas; College of Physicians and Surgeons, Baltimore, 1884; aged 78; died, September 16, of heart disease.

Wheeler Hayes Melvin, Los Angeles; University of Illinois College of Medicine, Chicago, 1905; aged 52; died, September 14, of pneumonia.

Dorothea A. Storck, Indianapolis; Hahnemann Medical College and Hospital, Chicago, 1913; aged 58; died, September 21, of acute nephritis.

Augustus P. Myers, Mobile, Ala.; Homeopathic Medical College of Missouri, St. Louis, 1888; aged 76; died, November 1, of arteriosclerosis.

George W. Bodey, North Lewisburg, Ohio; Kentucky School of Medicine, Louisville, 1892; aged 69; died, November 8, of heart disease.

William F. Quinlivan, Philadelphia; Maryland Medical College, Baltimore, 1907; aged 54; died, September 8, of cerebral arteriosclerosis.

Walter Wilbur, Lynden, Wash.; University of Michigan Medical School, Ann Arbor, 1881; aged 84; died, August 23, of heart disease.

F. C. William Obert, East Alton, Ill.; American Medical College, St. Louis, 1890; aged 71; died, October 16, of arteriosclerosis.

James Oscar Meharg, Fort Worth, Texas; Fort Worth School of Medicine, 1905; aged 58; died, September 21, of carcinoma.

William S. Price, Tangier, Ind. (licensed in Indiana in 1897); Civil War veteran; aged 90; died, October 28, of senility.

Herman Partsch, Berkeley, Calif.; University of California Medical Department, 1884; aged 84; died, September 6.

Correspondence

THE LANGUAGE OF MEDICINE

To the Editor:—The last paragraph of the editorial *The Language of Medicine* in the September 15 issue of *THE JOURNAL* is so important and interesting that more should be written about it.

Even if the language is far from perfect, an article written with the sincere desire to convey information may be interesting and hold the attention of its readers, as may also an article written to entertain. An informative medical article would hardly be suitable for displaying slang; but the writer is often guilty of an equally grave offense—the display of technical learning or high-sounding words.

A research worker who has made a profound study of a subject should not forget that the profession as a whole and even eminent scientists who specialize in other branches know little or nothing about what seems simple to him. When explaining the truth that he has discovered, he must discard every technical term possible and confine himself to simple good English if he is going to get his message across. He must remember that *THE JOURNAL* is sent to every country in the world and that in some places the doctors are not so well educated as in the United States. Our object must be to spread American culture.

The following paragraph taken from a study of yaws and syphilis will illustrate the point:

"The early metastatic polypapillomatous lesions in yaws are uniform to such an extent as to tend to monotony. The medical observer coming from a nontropical country will at once be reminded of multiple impetiginous. The metastatic polypapillomata are raised above the skin's surface seeming to fungate, much more than in syphilitic lesions. This is easy to understand considering their histopathology, i. e., an oedematous, verrucous (acanthotic) plasmoma, like the mother-yaw but of smaller size."

Three questions may be asked about this style of writing:

1. Does this paragraph convey a clear picture of the early symptoms of yaws to the average doctor who has not seen a case?
2. Is such a doctor able to clarify the paragraph by aid of a dictionary?
3. Is a trained medical writer able to reconstruct this paragraph so that it conveys a clear picture to the average doctor? If so, it would be interesting to see it done.

BERTEL SKOU, Manila, P. I.

COMPLICATIONS IN INJECTIONS OF VARICOSE VEINS

To the Editor:—In *Queries and Minor Notes* in *THE JOURNAL*, October 6, page 1088, a New York physician tells of having injected 3 or 4 minims (0.2 cc.) of 5 per cent sodium morrhuate into a leg vein and having the vein suddenly disintegrate, allowing the solution to become free in the tissues. Following this an ulcer developed. I too am at a loss to know what he means by a "sudden disintegration of the vein." In my seven years experience in this work, neither in my clinic nor in my private work have I ever seen such an occurrence. During the past year and a half we have used several hundred cubic centimeters of 5 per cent sodium morrhuate in my clinic without a slough. There have been several cases in which at least 0.1 to 0.2 cc. has been deposited in the tissues incident to the various accidents attendant on the injection treatment. Hard, tender to painful masses develop at these sites but none have broken down and sloughed as they did when the combined

sugar and salt solutions were used. In cases in which, accidentally, enough solution is injected into the tissues to form a wheal, it is our procedure to inject immediately 2 cc. of a sterile 1 per cent solution of procaine hydrochloride in a four point injection (0.5 cc. each) around the area. This not only serves as a diluent but also acts as an anesthetic to control the burning pain. A firm, pressure dressing is then applied over the area.

G. D. BRAND, M.D., St. Paul.

[The letter was referred to Dr. I. G. Frohman, who replies:]

To the Editor:—The word "disintegrate" was chosen because it describes better exactly the unusual occurrence that took place. I am certain that no sodium morrhuate previously entered the tissues. Earlier injections in the same patient were uniformly successful.

The small vein in question was about one-half by one-eighth inch in dimensions. Aspiration gave blood and the injection proceeded slowly as the vein swelled with the fluid. Suddenly the vessel just disappeared and the blood-colored liquid was free in the surrounding tissues. The patient screamed with pain and would allow no subsequent injection in the area to dilute and anesthetize.

A slough later followed, which was very slow to heal. The patient, who is of a hysterical make up, complained for weeks of intense and agonizing pain. She will allow no surgical treatment or pressure bandage but insists on ointments of varying types. Because of the long-standing pain, I have used butesin picrate, nupercaine and later sulphonated bitumen, scarlet red and balsam.

If there is any explanation for the long standing, severe pain and for the behavior of the venule, I should be glad to hear of it.

I. G. FROHMAN, M.D., New York.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

ARTERIOSCLEROSIS AND HYPERTENSION

To the Editor:—A man about 40 years of age has always had fairly good health except that a specialist in tuberculosis once made the statement that his lungs showed some fibrosis. A urologist later said that the urine showed shreds, and he gave prostatic massage treatments many times. The patient is zealous in the care of his diet and came to me in 1930 for a small exostosis-like body on the finger, which was roentgenographed with negative results for any solid growth, but it was noted on the film that the radial arteries were distinctly atheromatous, which condition had never been suspected by the heart specialist. I had a check up set of roentgenograms taken this year of both arms, which appear much the same as in 1931; I also had roentgenograms taken of the lower extremities, which show a similar condition of the arteries of lower extremities. He is in the best of health. There has never really been any definite focus of infection determinable. The blood pressure is about 130 systolic, 75 diastolic, but two years ago it was somewhat higher. As previously stated, the patient takes good care of himself in every way. The urine is normal. The Wassermann reaction is negative. The patient does not use whisky. The thing that concerns me is the outlook for a man with so definite an arteriosclerosis. He has asked me how long he will live. Are conditions such as described of frequent occurrence in men so young? Doubtless this condition has been present for many years. It would seem that a heart examination is incomplete without a roentgenogram.

M.D., California.

ANSWER.—The case described is typical of the often forgotten fact that arteriosclerosis of the larger arteries, with or without calcification, is an entirely separate entity from hypertensive disease. In the minds of many there exists a notable confusion of these two diseases. Arteriosclerosis involves the larger vessels, often with no abnormality of the arterial tensions, whereas hypertensive arterial disease involves the smallest arteries and arterioles. Despite the not infrequent coincidence of the two processes, their fundamental independence and individuality warrants emphasis.

The incidence of arteriosclerosis is difficult to evaluate (Sydenstricker, Edgar, in Cowdry, E. V.: *Arteriosclerosis*, New York, Macmillan Company, 1933, pp. 131-151). Arteriosclerotic

changes are more frequent in professional and business groups than in industrial and agricultural workers. The following data from studies regarding the age incidence of arterial thickening in white male and female policyholders afford a good general picture of the relation to age in those persons of moderate or better than moderate means:

Age Groups	Males, Per Cent	Females, Per Cent
20-29 years	6.4	3.2
30-34 years	7.8	5.6
35-39 years	10.0	8.0
40-44 years	12.8	11.1
45-49 years	16.1	15.7
50-54 years	22.9	23.6
55-59 years	28.3	28.4
60 and over	38.4	37.3

Of considerable interest is the lower incidence in females in the younger age groups; this difference disappears at about the average age of the appearance of the climacteric.

Statistical data on the death rate in arteriosclerotic individuals are unsatisfactory because of changing and unstandardized terminology, inaccuracy of diagnosis unless necropsies have been made, and extremely variable methods of tabulation. In the United States registration area the federal Bureau of the Census in 1928 includes arteriosclerosis as a cause of death under the vague and almost meaningless and useless term "other diseases of the arteries." The total mortality rate for all ages was 29 per hundred thousand. Of these deaths 59 per cent occurred in persons 75 years of age or older and 25 per cent in persons in the decade from 65 to 74 years. Thus, 83 per cent of deaths attributable to arteriosclerosis occur after 65 years of age. Overweight, according to the insurance investigations, greatly increases the mortality rate (Dublin, L. I.: *Human Biology*, May 1931, p. 170).

In view of the fact that a little over 12 per cent of men over 40 years of age give evidence of arterial thickening, the case cited cannot be considered unusual. The etiology of this disease is still extremely obscure, which makes prognostication difficult. The fact that the man showed no evidence of cardiac or renal disturbance and had a negative blood Wassermann reaction (which, of course, does not prove the absence of syphilis) and a normal arterial tension, should be encouraging factors in evaluating the prognosis. It is not known whether the frequency of arteriosclerosis is increasing, especially in younger persons. In this connection it may be appropriate to mention that presenile calcification of the sternal cartilages is being noted by roentgenologists far more frequently than formerly. Calcification of these cartilaginous structures is being observed quite commonly in the chest films of young people between 20 and 40 years of age. Perhaps, as a pure and unconfirmed speculation, the far more general and liberal use of vitamin concentrates and sunshine may be regarded as a possible contributing factor to such an unusually early tendency to the deposition of calcium.

Persons may live in good and vigorous health for many years despite marked calcification of the arteries of the extremities. The fact that such changes are demonstrable in the extremities does not necessarily imply that similar or as extensive degeneration has involved the cerebral, cardiac or visceral vessels. This patient should have annual or semiannual electrocardiographic studies, which may give warning of involvement of the coronary arteries.

CORPORA LUTEA IN HEMOPHILIA—TOXOID IN DIPHTHERIA—VERSION IN OBSTETRICS

To the Editor:—1. Does the use of corpora lutea in a male child with hemophilia tend to control this disturbance? 2. Is there a serum or vaccine that will give a life immunity from diphtheria? 3. Do you consider that there is a definite and rather rapid trend toward the use of version to supplant the Scanzoni maneuver in the treatment of persistent occipitoposterior position in obstetrics? Please omit name.

M.D., Alabama.

ANSWER.—1. There are conflicting reports concerning the use of corpus luteum in cases of hemophilia. Hynek (*Ann. de méd.* 14:122 [Aug.] 1923) observed normal clotting time of the blood in hemophilia after the use of corpus luteum. On the other hand, Neihans (*Schweiz. med. Wchschr.* 60:18 [Jan. 4] 1930) found that implantation of whole ovary produced no benefit in this disease but that when pieces of ovary without corpora lutea were implanted there was improvement. Interest in the use of ovarian substance in hemophilia was recently aroused by the reports of Birch (*Proc. Soc. Exper. Biol. & Med.* 28:752 [April] 1931; Hemophilia and the Female Sex Hormone, *THE JOURNAL*, July 25, 1931, p. 244; Hemophilia, *ibid.* Nov. 5, 1932, p. 1566). Among nineteen cases of hemophilia treated with ovarian substance, nine were considerably improved, nine showed some betterment and only one failed

to respond to treatment. Following the report of Birch a few papers were published reporting improvement in cases of hemophilia after the use of ovarian preparations, but other reports indicated that ovarian substance failed to give relief for this blood dyscrasia. Thus Stetson, Forkner, Chew and Rich (Negative Effect of Prolonged Administration of Ovarian Substances in Hemophilia, *THE JOURNAL*, April 7, 1934, p. 1122) reported on the use of ovarian substance or estrogenic substance in seven cases of hemophilia. In spite of the fact that large amounts of eight different preparations were used, in no instance was the coagulation time of the venous blood found to be depressed as the result of such therapy, nor was any clinical improvement noted that could be attributed to the ovarian therapy.

2. There is no serum or vaccine that will give life immunity from diphtheria, but there is a toxoid (anatoxin-Ramon) that will tend to do so in the majority of cases. The toxoid is far more satisfactory for purposes of immunization than diphtheria toxin-antitoxin.

3. Since Potter reintroduced and popularized the operation of version and extraction, a large number of these operations have been performed. While a few individuals deliver a high proportion of their patients by this maneuver, nearly all obstetricians resort to this operation only for definite obstetric indications. In the type of case cited, occiput posterior, version has become popular in the cases in which the fetal head is not engaged. This popularity is deserved because usually, when the head is high in the pelvis, delivery can be accomplished only by a difficult high or mid forceps delivery. In such cases, version and extraction are preferable. Of course neither a forceps operation nor version and extraction should be attempted if there is a disproportion between the fetal head and the pelvis. In cases of occiput posterior in which the head is engaged, the general practice is to rotate the occiput anteriorly with forceps or manually. DeLee and his associates advocate manual rotation, while Bill is the most prominent authority in favor of instrumental rotation. The same good end results may be obtained with either procedure, provided one makes an accurate diagnosis and uses appropriate care and skill in the delivery. Green soap as a lubricant in the vagina is of valuable assistance. When satisfactory rotation with the hand or instrument proves impossible and especially when the head rests on the perineum, it is preferable to deliver the head as an occiput posterior. However, an extensive episiotomy must be made to prevent a deep laceration. When the head is well engaged, it is not good practice to displace it and perform a version.

COMPLEMENT FIXATION TEST IN TUBERCULOSIS

To the Editor:—Could you discuss through *THE JOURNAL* the value of the complement fixation test for tuberculosis, both in regard to prognosis and in regard to diagnosis? Kindly omit name and address.

M.D., New York.

ANSWER.—The literature on the complement fixation test in tuberculosis is voluminous. Among the hundreds of articles on this subject there are those which come to the conclusion that the complement fixation test approaches 100 per cent in diagnosis and prognosis. On the other hand, some authors conclude that the test is of but little value either in diagnosis or in prognosis. Between the two extremes are numerous articles giving various evaluations to the test.

The positive test is thought to be dependent on absorption from the lesion, since in the absence of absorption there is no antibody formation. Therefore, before absorption occurs there is no antibody content. The antibody content is usually low when absorption begins but increases with the increase of absorption from the focus and decreases as the focus comes under control and less absorption takes place. Thus, the test may be looked on as one that aids in the determination of the activity of the disease; that is, the positive reaction presents reasonably good evidence that there is some absorption from the lesion, and a negative test indicates that no absorption is taking place.

However, there are some factors that may inhibit the reaction. It is also true that in far advanced terminal cases the antibody curve rapidly falls and the test may become negative. Thus, a tuberculous lesion may exist over a considerable period of time with the complement fixation test negative, owing to the fact that there is little or no absorption. Again, as the lesion is coming under control and absorption ceases, the test becomes negative, yet the lesion is still present and capable of reactivating. In the childhood type of tuberculosis there is little or no absorption in most cases, and the complement fixation test has been found to be of little or no value. Certainly the test is not as final as the Wassermann test in the diagnosis of syphilis.

It is often stated that the complement fixation test in tuberculosis is of greatest value when negative; for example, in the differential diagnosis of chest diseases, such as abscess, bronchiectasis and tumor. In recent years other valuable diagnostic aids, such as the bronchoscope, have been added to the armamentarium. After all, the use of this instrument, and the biopsy that is made possible through it, often gives the final word in diagnosis of nontuberculous chest conditions, which no other means can afford. The complement fixation test is of less value in the diagnosis of tuberculosis in other parts of the body than the lungs, since in these forms of the disease it is not so frequently positive.

In prognosis, particularly among advanced cases of pulmonary tuberculosis, a strongly positive complement fixation test is a better indication than one that reacts weakly. When the test is carefully performed, it is positive in from 60 to 80 per cent of cases of tuberculosis. Obviously, a test that fails in from 20 to 40 per cent cannot be of great value in diagnosis or prognosis. Therefore, although it is used by a number of workers it is of uncertain value, since it does not determine with certainty the clinical activity of all lesions and since it may be negative in very definite cases of tuberculosis and positive in cases with no demonstrable disease. For this reason it is not a test that is depended on much by the clinician, particularly since new diagnostic aids are resulting in less need for such a test. However, considerable research on the complement fixation test is now in progress, and it is possible that refinements in technic or new methods may bring it to a more valuable position than it holds at present.

ECZEMATOID RINGWORM INFECTIONS

To the Editor:—I have a patient, a woman, aged 29, a stenographer, whose hands, especially the palms, and feet are infected by a papular rash with oozing and intense itching. She has been under the treatment of dermatologists for seven months. No results have followed the use of hot permanganate baths, Burrow's solution of various ointments. Skin tests and blood examination are negative. Is the diagnosis ringworm, trench foot or chronic eczema? What can be done?

M.D., New Jersey.

ANSWER.—The occurrence of a palmar eruption, with extension to the dorsum of the hands and associated involvement of the feet, as described, is a part of the picture seen in eczematoid ringworm infections. In addition to a "papular rash, with oozing and intense itching," one also notes, in these cases, deep-seated vesicles, scaling and maceration between the toes. In many the hand involvement is a toxic (dermatophytid) eruption, secondary to the involvement of the feet. It is essential that all active infection of the feet be completely cleared if one is to guard against recurrence. The contributory factor of external irritants and sensitivity to certain foods may also play a part in the causation of the eruption. The continuance is suggested of warm compresses of 1:3,000 potassium permanganate solution to the hands and feet, morning and night. After the night compress, the parts should be covered thoroughly with a 3 to 5 per cent crude coal-tar ointment, which should be washed off in the morning with olive oil. After the active infection is controlled, any residual scaling dermatitis may be treated with half-strength Whitfield's ointment, to which may be added from 3 to 5 per cent of precipitated sulphur. A dusting powder may be used between the toes during the day, and the use of an iodine paint to the scaling patches in the morning, such as 3 per cent iodine in benzene. X-rays in fractional doses are a valuable adjunct in treating these cases. One should guard against reinfection by the wearing of white cotton anklets, which should be changed frequently and boiled before wearing again.

DRUGS IN TIC DOULOUREUX

To the Editor:—Please tell me what drugs are most effective in the treatment of tic douloureux? Please omit name if published.

M.D., North Carolina.

ANSWER.—The drug treatment of tic douloureux is notoriously unsatisfactory. Nevertheless, it should be undertaken before injection treatment and surgery are advised. With somewhat of an attempt at causal therapy, one should employ quinine (from 1 to 2 Gm. daily for a considerable time) if malarial, or iodide if syphilitic etiology is suspected, iron and arsenic if there is anemia, sodium salicylate (0.6 Gm. every hour or two for a few days, then three times daily) with sodium bicarbonate if a rheumatic causation might exist, or castor oil (from 15 to 30 cc. daily for several weeks, if intestinal intoxication needs to be excluded). From a standpoint of what might possibly be called alternative therapy, strychnine hypodermic injections (from 2 mg. gradually increasing to 12 mg. daily), cannabis (fluidextract from 0.1 to 0.2 cc. or even

more three times daily); or fluidextract of gelsemium (0.05 to 0.2 cc. or more every two to four hours until dizziness, double vision, dilatation of the pupils or dropped lids become manifest) might succeed in changing conditions in the nervous system so as to result in at least temporary improvement. The latest addition to the armamentarium in this condition is trichlorethylene, of which from 20 to 25 drops placed on a piece of gauze should be inhaled three or four times daily for a period of from four to six weeks before being discontinued. During the inhalation the patient should be in a recumbent position, as dizziness or drowsiness may be produced. The use of opiates is strictly contraindicated, as there is greater danger from the habit engendered thereby than there would be from destructive injections into the nerves or surgical evulsion of the nerves.

IRRADIATION OF FEMALE PELVIS

To the Editor:—A Catholic priest, administering to his people in a local Catholic hospital, has asked me for information which he can quote with authority concerning the effect of x-rays and the quantities of x-rays that can be administered to the pelvis especially, and to any other part of the body of a pregnant woman. I will appreciate receiving your answers to these questions, and also references to which this party may refer to back up his interpretations.

M.D., Iowa.

ANSWER.—Regardless of religious belief, irradiation of the pelvis of a pregnant woman or the fertilized egg is a serious procedure and should never be used unless the pregnancy is to be terminated. The results of this procedure are usually retarded cerebral development known as microcephaly. D. P. Murphy (Ovarian Irradiation, *Surg., Gynec. & Obst.* 47:201 [Aug.] 1928) gives the incidence of defectives as 61.3 per cent following irradiation of pregnant animals. In a later paper (*Surg., Gynec. & Obst.* 48:766 [June] 1929) the same author reports fifty-three pregnancies in which postconception pelvic radium or roentgen irradiation was administered. Abortion occurred in twenty-three instances (43.4 per cent). Twelve per cent of the thirty full term pregnancies presented some more or less serious disturbance of health or development. These defects in many instances were quite serious and tended to conform somewhat to a type. In summing up his observations in the litters of thirty-four female albino rats irradiated when pregnant Murphy concludes (*Surg., Gynec. & Obst.* 50:861 [May] 1930) that the deforming of five offspring was due to the radiation, as similar deformities have not been duplicated in a series of 125,000 nonirradiated control animals.

In applying radiation to other parts of the body of a pregnant woman, great care must be exercised to screen the pelvis. If this is carried out, no effect is noticed on the offspring.

Roentgenographic studies of the pregnant pelvis to determine anomalies of the mother or the fetus are not harmful.

ESTROGENIC SUBSTANCES IN BREAST ATROPHY

To the Editor:—A 25 year old white married mother, one year after a normal delivery of her first child, presents herself with a marked atrophy of both breasts. During her early puerperium she had a breast abscess, which necessitated incision and drainage and which interrupted further nursing. Her return menstrual history has been normal in every way. There is now just a slight premenstrual enlargement of both breasts, which begins about seven days before and is maintained throughout the period (five days). Will female sex hormone as obtained in antuitrin-S or that obtained in the ovarian product theelin restore the normal consistency and size of the breasts? Which one is here indicated? It seems peculiar to me that, if there is here an adequate ovarian hormone output as judged from the uterine response and normal menstrual history and therefore behind it all a proper anterior pituitary function, there should nevertheless be such an abnormal mammary response despite the history of breast abscess. Please omit name.

M.D., New York.

ANSWER.—"Female sex hormone" is the name applied by Frank to the estrogenic principle of the ovary. It is not applicable to "antuitrin-S," which is a commercial extract of the anterior pituitary-like gonadotropic principle obtained from the urine of pregnancy. It is preferable for many reasons not to employ the term "female sex hormone" even for theelin; this too is obtained from the urine of pregnancy.

It has been reported that injection or ingestion of estrogenic substance (theelin, theelol, Amniotin and so on) may produce hypertrophy of the breasts. It does not follow from the fact that the patient mentioned has apparently normal menstruation that the normal amount of estrogenic substance is produced by her ovaries; apparently normal bleeding can be induced by amounts of estrogenic principle well below the threshold for the production of normal progestational proliferation of the endometrium. The only way to determine whether adequate amounts are produced is to perform assays on blood

and urine repeatedly during the menstrual cycle, as advocated by Frank. While theoretically the best way to produce mammary enlargement would be to stimulate the ovaries to produce more estrogenic substance, the action of anterior pituitary or anterior pituitary-like principles is not sufficiently controllable to warrant their trial in this case.

Estrogenic substance need not necessarily be injected, as its effects can be obtained by oral administration of rather large doses. It is probable that any effect that may be obtained will not be permanent and that continuous administration of the preparation will be necessary; the disadvantages of this must be kept in mind.

INFECTION OF GLANDS OF THE NECK

To the Editor.—I am writing for some advice regarding a condition that has recently come under my observation. The patient is a woman, aged 21. At the age of 4, a lump was noticed on her neck on the right side anterior to the sternomastoid muscle. This was opened and drained from time to time. The tumor mass shifted over a period of years until it finally came to the midline just over the manubrium. Three years ago it was again incised and drained, and it appeared to heal completely. There was no sign of it to eighteen months, when a small lump appeared just below the lobe of the right ear. It enlarged to the size of an egg, and the patient had great difficulty in opening her jaws. A surgeon incised this mass and curetted out a quantity of cheesy material. The symptoms subsided for about six months, but during the past ten months there has been a constant purulent discharge from an opening one inch anterior to the lobe of the right ear. There have been times when a clear watery fluid flowed out in considerable quantity. This was especially noticeable at meal time. Otherwise the patient appears to be in good health. What would you advise therapeutically?

JOHN A. MOONEY, M.D., Kenton, Ohio.

ANSWER.—The diagnosis probably lies between tuberculosis or a pyogenic infection of the glands of the neck and a branchial cyst. The cysts secrete a sebaceous material and are usually lined by squamous epithelium. They are single and usually lie along the anterior border of the sternocleidomastoid muscle. The center of the cyst is usually about the level of the great cornu of the hyoid.

It is possible that the condition may be a pyogenic or non-tuberculous infection of some chronic type, such as syphilis or actinomycosis. The usual laboratory tests should be made to rule these out, including examination of the discharge and blood tests. While the origin is almost certainly in the lymph glands, owing to its change in location and repeated breaking down, it is possible that the salivary glands may be involved.

Systemic tests are not satisfactory for tuberculosis of the glands, but examination and injection into a guinea-pig of the discharge should establish the diagnosis. If these tests are negative, a biopsy should be made and a microscopic examination of the tissue.

The treatment must depend on the condition. Careful search must be made for some focus of infection in the nose and throat, such as infected tonsils and teeth or sinuses. These infections should be eliminated.

General measures are often of value. Locally, roentgen and light treatment may relieve the condition; if not, further surgery may be necessary. But the facial nerve should be avoided.

CHOLECYSTIC DISEASE

To the Editor.—Please let me know whether a diseased gallbladder can spontaneously recover after several years and become a normal gallbladder. My only daughter, aged 21, has suffered a great deal with many pains and because of her illness has virtually become an invalid. In February 1931 a physician roentgenographed her and besides finding a visceroptosis in a gastro-intestinal series saw her gallbladder outlined and warned me of future gallbladder trouble. She had a long double-kinked and movable appendix. In October 1932 Dr. Edward Blaine found a subnormal gallbladder in that its concentrating power was considerably reduced and the distended appearance was compatible with a hydrops. A "low grade gallbladder" was present. In view of the roentgen examination of February 1931, the present examination is distinctly corroborative. Two months ago a good internist made a roentgen examination and diagnosed a normal gallbladder filling and emptying normally. The appendix did not visualize. My daughter is still a sick person and gradually she is becoming more helpless. A splendid local surgeon has not operated for two years but my child is worse. She had spells of epigastric pain and has general depression. M.D., California.

ANSWER.—Although reference is made only to the report of the roentgen examination of the gallbladder in 1931, the patient presumably had attacks of upper abdominal pain simulating biliary tract disease which led to this examination. In the last sentence it is stated, "My child is worse. She had spells of epigastric pain." If it is assumed that these attacks of epigastric pain simulate biliary colic and the patient is becoming worse, abdominal exploration, particularly of the gallbladder, stomach and duodenum, should be carried out. In a problem of diagnosis, the patient's clinical history, her general condition,

and the result of the physical examination should be the determining factors in influencing one's decision as to whether or not intra-abdominal disease exists.

In most cases, roentgen examination of the gallbladder is helpful, when positive, as corroborative evidence of cholecystic disease. However, filling and emptying of the gallbladder do not exclude the possibility of cholecystitis or cholelithiasis.

EROSION OF TEETH

To the Editor.—Will you kindly tell me the underlying causes and appropriate treatment of erosion of the teeth occurring at the gum line? I have seen a number of cases in which the enamel is apparently worn off just above the gum line with no evidence of infection or irritation of either gums or teeth. This condition occurs in apparently healthy people who evidently employ sufficient mouth hygiene. I have asked a number of dentists about this condition and have received as many different answers, all of which have been unsatisfactory so far as revealing the cause. Kindly omit name and address. M.D., New York.

ANSWER.—The cause or causes of erosion of the teeth are not fully understood. There is one variety that is produced by the abuse of the teeth in cleaning them through improper use of the brush and the employment of abrasive dentifrices. Another variety is considered to be the effect of secretions either from the parotid or from the mouth mucous glands. Such secretions in persons suffering from this form of erosion are believed to be capable of dissolving enamel and dentin and tend to stagnate in the groove between the gums and the teeth in places opposite the opening for the discharge of the parotid secretion. The former condition is easily managed but the latter, although likely to be associated with fluctuations, does not seem to respond favorably to any known form of treatment. If fillings are placed in the defects, erosion recurs around the filling margins; the use of alkaline preparations is not associated with any considerable degree of improvement, and the effort so far to control the condition by diet or drug therapy has been equally unavailing.

GOLD TRIBROMIDE IN WHOOPING COUGH

To the Editor.—In THE JOURNAL, July 28, I note a question regarding use of gold tribromide for whooping cough. Will you please inform me what preparation is used and the dosage for children? Kindly omit name. M.D., Iowa.

ANSWER.—Gold tribromide is slowly soluble in water and may be prescribed for very young children in doses of 0.002 Gm. and to larger children in doses of from 0.003 to 0.006 Gm. three times daily, each dose dissolved in a teaspoonful of distilled water. Its virtues are not yet established.

CLIMATE FOR SINUSITIS

To the Editor.—In Queries and Minor Notes in THE JOURNAL, October 13, page 1175, Dr. Henry Wallace of New York, under "Climate and Sinusitis," says "Florida also is not a good place" after finding (in one case) San Diego not agreeable. Let me remark after having lived here in San Diego since 1921, and in Florida twenty years in eye, ear, nose and throat work, that, as in all other things medical, there are patients helped here and patients helped in Arizona, and many in Florida, if the physician knows how to segregate them. Patients in whom drainage is better on rainy days are helped in Florida. Those with much secretion are better in Arizona or Texas, and ordinary patients with neither extreme are better in southern California. Of course I am presuming that all medical and surgical treatment has been given and every assistance besides that of climate first resorted to. It is often a vital matter to patients to change environment, and this should never be done thoughtlessly. I say it unobtrusively that few physicians have had the many years of observation in sinus cases that I have had in both Florida and California, and such observation should have some weight. I do agree with Dr. Wallace that all patients should remain in the new environment at least two years for results.

FREDERICK J. WALTER, M.D., San Diego, Calif.

FUNCTION OF THE EPIGLOTTIS IN SPEECH

To the Editor.—In the answers to the question on the function of the epiglottis in Queries and Minor Notes in THE JOURNAL, September 22 and November 3, no mention was made of the conclusions of G. O. Russell (Speech and Voice, New York, Macmillan Company, 1931):

The tip of the epiglottis may lie well back against the wall of the pharynx (p. 175). . . . It assumes characteristic positions in the production of the various vowels (p. 145). The tubercle, cushion or pulvinar of the epiglottis functions as a soft-surfaced filter to lower pitch and mellow the quality in tones when cooperating with the cartilages of Wrisberg (p. 175). When the tonal quality is distinctly nasal, the cushion of the epiglottis is often seen almost to close on the cartilages of Wrisberg (p. 240).

It seems to me that this information would be the most pertinent to the speech teacher.

CHARLES H. VOELKER, Columbus, Ohio.
Professor of Speech Pathology, Capital College.

Council on Medical Education and Hospitals

COMING EXAMINATIONS

ALABAMA: Montgomery, Jan. 7. Sec., Dr. J. N. Baker, 519 Dexter Ave., Montgomery.

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY: *Written (Group B candidates)*. The examination will be held in various cities throughout the country, April 29. *Oral (Group A and Group B candidates)*. New York, June 10. Sec., Dr. C. Guy Lane, 416 Marlborough St., Boston.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY: *Written (Group B candidates)*. The examination will be held in various cities of the United States and Canada, March 23. *Final oral and clinical examination (Group A and Group B candidates)*. Atlantic City, N. J., June 10-11. Group B application lists close Feb. 23 and Group A application lists close May 10. Sec., Dr. Paul Titus, 1015 Highland Bldg., Pittsburgh.

AMERICAN BOARD OF OPHTHALMOLOGY: Philadelphia, June 10. *Application must be filed at least sixty days prior to date of examination*. Sec., Dr. William H. Wilder, 122 S. Michigan Blvd., Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY: New York, June 8. Sec., Dr. W. P. Wherry, 1500 Medical Arts Bldg., Omaha.

ARIZONA: *Basic Science*. Tucson, Dec. 18. Sec., Dr. Robert L. Nugent, Science Hall, University of Arizona, Tucson. *Medical*. Phoenix, Jan. 2-3. Sec., Dr. J. H. Patterson, 320 Security Bldg., Phoenix.

COLORADO: Denver, Jan. 18. Sec., Dr. Wm. Whitridge Williams, 422 State Office Bldg., Denver.

DELAWARE: Wilmington, Dec. 11-13. Sec., Dr. Joseph S. McDaniel, Dover.

DISTRICT OF COLUMBIA: *Basic Science*. Washington, Dec. 27-28. *Medical*. Washington, Jan. 14-15. Sec., Commission on Licensure, Dr. W. C. Fowler, 203 District Bldg., Washington.

ILLINOIS: Chicago, Jan. 22-24. Superintendent of Registration, Department of Registration and Education, Mr. Eugene R. Schwartz, Springfield.

IOWA: Des Moines, Jan. 3-5. Dir., Division of Licensure and Registration, Mr. H. W. Grefe, Capitol Bldg., Des Moines.

KANSAS: Topeka, Dec. 11-12. Sec., Dr. C. H. Ewing, Larned.

MARYLAND: *Regular*. Baltimore, Dec. 11-14. Sec., Dr. Henry M. Fitzhugh, 1211 Cathedral St., Baltimore. *Homoeopathic*. Baltimore, Dec. 11-12. Sec., Dr. John A. Evans, 612 W. 40th St., Baltimore.

MINNESOTA: *Basic Science*. Minneapolis, Jan. 2-3. Sec., Dr. J. Charney McKinley, 126 Millard Hall, University of Minnesota, Minneapolis. *Medical*. Minneapolis, Jan. 15-17. Sec., Dr. E. J. Engberg, 350 St. Peter St., St. Paul.

NATIONAL BOARD OF MEDICAL EXAMINERS: *Parts I and II*. The examinations will be held in medical centers where there are five or more candidates, Feb. 13-15. Ex. Sec., Mr. Everett S. Elwood, 225 S. 15th St., Philadelphia.

NEBRASKA: *Basic Science*. Omaha, Jan. 8-9. Dir., Bureau of Examining Boards, Mrs. Clark Perkins, State House, Lincoln.

NEW YORK: Albany, Buffalo, New York and Syracuse, Jan. 28-31. Chief, Professional Examinations Bureau, Mr. Herbert J. Hamilton, Room 315 Education Bldg., Albany.

NORTH DAKOTA: Grand Forks, Jan. 1-4. Sec., Dr. G. M. Williamson, 4½ S. 3d St., Grand Forks.

OKLAHOMA: *Reciprocity*. Oklahoma City, Dec. 11. Sec., Dr. J. M. Byrum, Mammoth Bldg., Shawnee.

OREGON: Portland, Jan. 2-4. Sec., Dr. Joseph F. Wood, 509 Selling Bldg., Portland.

PENNSYLVANIA: Philadelphia, Jan. 8-12. Sec., Board of Medical Education and Licensure, Mr. W. M. Denison, 400 Education Bldg., Harrisburg.

RHODE ISLAND: Providence, Jan. 3-4. Dir., Public Health Commission, Dr. Lester A. Round, 319 State Office Bldg., Providence.

SOUTH DAKOTA: Pierre, Jan. 15-16. Dir., Division of Medical Licensure, Dr. Park B. Jenkins, Pierre.

TENNESSEE: Memphis, Dec. 20-21. Sec., Dr. H. W. Qualls, 130 Madison Ave., Memphis.

WASHINGTON: *Basic Science*. Seattle, Jan. 10-11. *Medical*. Seattle, Jan. 14-16. Dir., Department of Licenses, Mr. Harry C. Huse, Olympia.

WISCONSIN: *Basic Science*. Milwaukee, Dec. 15. Sec., Prof. Robert N. Bauer, 3414 W. Wisconsin Ave., Milwaukee. *Medical*. Madison, Jan. 8-10. Sec., Dr. Robert E. Flynn, 401 Main St., LaCrosse.

THE TRAINING OF PHYSICIANS IN RUSSIA

Decree of the Central Executive Committee,
U. S. S. R., Sept. 3, 1934

The following decree, published in *Ekonomicheskaya Zhizn*, Moscow, September 4, has been translated by Peter T. Swanish, Ph.D., of Loyola University, Chicago:

The Central Executive Committee, U. S. S. R., notes that despite the general increase in the number of students in higher institutions of medical education, from 26,100 in 1928 to 48,000 on Jan. 1, 1934, and the growth in the number of such institutions throughout the Soviet Union from twenty-five to forty-nine, the training of physicians, as a consequence of poor administration by the People's Commissars of Health of the Federated Republics, is unsatisfactory.

In the latter connection, the People's Commissars of Health have failed to give sufficient attention to the training of "attending practitioners" of medicine required in urban and rural

localities, while at the same time there has been an extraordinary increase in the number of students receiving training in the preventive branches (doctors of hygiene and the like).

Education in the medical schools has not provided a fundamental and general training. The fundamental medical disciplines (normal and pathologic anatomy and physiology, biologic chemistry, clinical subjects) have not been given a sufficiently important place in the curriculum. Students have not been adequately supplied with textbooks despite opportunities for revision of courses and the adoption of improved methods of foreign specialists.

Within recent years, clinics of medical institutions where research in medicine is concentrated have lost their didactic rôle and have become ordinary hospitals; and with respect to equipment and class of patients, their organization does not meet the needs of medical education. Scientific laboratories and lecture halls and anatomy rooms are insufficient in relation to the number of students; laboratory equipment is worn out and has not been adequately maintained or replaced.

For the purpose of eliminating the intolerable conditions that exist in the education of physicians, the committee:

1. Decrees an increase in the number of physicians in the country to provide for better care of urban and village population, the number of students to be admitted to higher institutions of medical training being fixed as follows: 1934, 15,610; 1935, 23,900; 1936, 30,600; 1937, 33,500.

2. Decrees: (a) The establishment in all medical institutions in the Soviet Union, for the training of practicing physicians, of faculties in therapeutics, surgery and obstetrics-gynecology in the fifth year of the medical course.

(b) The organization of faculties for the training of pediatricians in fourteen higher institutions of medical education.

(c) The organization of faculties in sanitation and hygiene, bacteriology-epidemiology and food sanitation, the specialization of physicians in these branches to begin in the fifth year, in ten higher institutions of medical education.

(d) A five-year course in all the foregoing institutions and faculties.

3. Decrees the establishment of the following proportions in the distribution of students as between different faculties (in all the republics): general medicine, 75 per cent; pediatrics, 15 per cent; sanitation and hygiene, 10 per cent.

4. Decrees specialization in the various branches of medicine (obstetrics, gynecology, eye, ear, nose and throat, and so on) and the improvement in qualifications of general practitioners, to be carried out as follows:

(a) Continuance of status as intern or clinical assistant in approved institutions and hospitals.

(b) The pursuit of courses of study in special branches of medicine by physicians attached to urban industry.

(c) Compulsory attendance once every three years of lectures and courses in institutions for medical training by all physicians practicing in rural localities and remote settlements, and the payment of stipends covering living costs and the usual compensation of such physicians.

5. (a) Decrees and considers as expedient the preparation of practicing physicians of the second grade in evening courses covering a five-year period.

(b) Forbids the training of physicians by means of correspondence courses.

6. Instructs the People's Commissars of Health of the Federated Republics to submit by Oct. 1, 1934, a new curriculum and program of study.

7. Decrees the compulsory examination by the state of all students completing courses in higher institutions of medical education. Such examination must be given by special examining boards appointed by the People's Commissars of Health of the Federated Republics.

8. Instructs the People's Commissars of Health of the Federated Republics to supply on time the issue of textbooks for medical schools for the year 1934-1935.

9. Authorizes the appropriation from the state budget, from Jan. 1, 1935, of the necessary financial resources for improving clinical instruction.

10. Authorizes, as of Sept. 1, 1934, additional compensation for senior teaching staffs in clinics for scientific research.

11 Authorizes a more rational and planned use of persons completing medical education and their distribution as between republics, regions and territories of the Soviet Union

12 Instructs the Soviet of People's Commissars, U S S R, to reexamine the question of additional appropriations for medical education for the year 1934 and for the years 1935-1937

A CHERVAKOV
A ENUKIDZE

President and Secretary, respectively, Central
Executive Committee, U S S R

Colorado July Report

Dr William Whitridge Williams, secretary, Colorado State Board of Medical Examiners, reports the written examination held in Denver, July 3-6, 1934. The examination covered 8 subjects and included 80 questions. An average of 75 per cent was required to pass. Fifty-four candidates were examined, 53 of whom passed and 1 failed. Twelve physicians were licensed by endorsement. The following schools were represented:

Indiana June Examination

Dr William R. Davidson, secretary, Indiana State Board of Medical Registration and Examination, reports the written examination held in Indianapolis, June 19-21, 1934. The examination covered 16 subjects and included 100 questions. An average of 75 per cent was required to pass. One hundred and thirty-nine candidates were examined, 135 of whom passed and 4 failed. The following schools were represented:

School	PASSED	Year Grad	Per Cent
Georgetown University School of Medicine		(1934)	83

Book Notices

Bronchoscopy, Esophagoscopy and Gastroscopy. A Manual of Peroral Endoscopy and Laryngeal Surgery. By Chevalier Jackson M.D. Sc.D., F.A.C.S., Professor of Bronchoscopy and Esophagocopy, Temple University, and Chevalier L. Jackson A.B., M.D. M.Sc., Professor of Clinical Bronchoscopy, Temple University. Third edition. Cloth. Price \$9. Pp. 485 with 240 illustrations. Philadelphia & London: W. B. Saunders Company, 1934.

In this edition, gastroscopy is not only mentioned in the title but more freely discussed in the text. The authors have extended their investigations in this field and with the help of the new Wolf-Schindler flexible gastroscope have brought to light many interesting facts. This instrument at present, unfortunately, is too expensive for the average bronchoscopist. Nevertheless its use, where available, is likely to lead to new observations which may prove of far reaching value to internists and surgeons. This entire chapter is intensely interesting. The new edition is considerably larger than the previous one. Many of the old illustrations have been replaced and new ones added. Also there are several additional colored drawings in the inimitable style of the elder Jackson, all delightfully graphic as usual. The chapters on diseases of the tracheobronchial tree and esophagus are more ample than in the previous edition and include the latest information on the subject. Physical examinations and roentgen studies are again emphasized and gone into thoroughly. The subject of tracheotomy is as complete as one could possibly desire and may be read and reread with profit not only by the surgeon but by interns and nurses as well. Among the topics that have been amplified are the care of chronic tracheal stenosis, the treatment of esophageal diverticula and the repair of tracheal fistulas. From the numerous types of operations suggested in these conditions the authors have selected only those which in their experience have yielded successful results and they have presented them with clarity and brevity. They offer a welcome guide to the perplexed laryngologist who may see these cases only occasionally. All in all this work is easily the foremost of its kind. Its text is never ambiguous, its illustrations are numerous and appropriate, and its scope is all embracing. Based as it is on vast experience, keen observation and thorough study, it lacks nothing that any endoscopist might require of a textbook.

Human Sterility: Causation, Diagnosis, and Treatment. A Practical Manual of Clinical Procedure. By Samuel Raynor Meaker M.D., Professor of Gynecology, Boston University School of Medicine. Medical Aspects of Human Fertility Series issued by the National Committee on Maternal Health. Inc. Cloth. Price \$4. Pp. 276 with 27 illustrations. Baltimore: Williams & Wilkins Company, 1934.

To those familiar with Meaker's former contributions to the subject of sterility, the present work will indeed be welcome. Published under the auspices of the National Committee on Maternal Health, the book represents a contemporary aspect of the subject presented in a simple, direct and acceptable form. The major portion of it is devoted to the causation and diagnosis of sterility and is described in accordance with the plan adopted by Meaker and his associates for the group study of married couples. Complete outlines are given for study and analysis of causative factors in both partners, and the various steps in procedure are briefly but adequately discussed. The conception that fertility and sterility represent respectively success or failure in human matings is stressed, the results of the union of male and female elements rather than a consideration of the individuals separately is emphasized. The fertility threshold is explained. The last quarter of the book is devoted to treatment, in which a most conservative and highly commendable attitude is adopted. Radical surgical treatment as has been handed down year after year in textbooks on gynecology and urology is completely debunked, and only the most rational procedures are advocated. In regard to endocrine gland treatment, the author has deemed it advisable to mark time, in the light of the present state of knowledge and experience in this field. Thyroid gland therapy alone is advocated in cases warranting its use, carefully controlled by repeated basal metabolic tests. The book will be found to fill a real need in the medical literature and should be widely read by the profession at large. A criticism that may justly be mentioned is a paucity of illustrations, which for the general medical reader are always

desirable and instructive. The limited references to the published literature on the subject of sterility may be justified by the fact that the book is based largely on the author's own clinic experience.

Nephritis and Allied Diseases: Their Pathogeny and Treatment. By Robert Platt, M.D., M.R.C.P., Physician, Royal Infirmary, Sheffield. Cloth. Price, \$2.75. Pp. 166, with 8 illustrations. New York & London: Oxford University Press, 1934.

The object of this book is briefly to present, in textbook style, what the author has found of most practical value in existing knowledge of Bright's disease. The book is not intended as a first introduction to the physiology or pathology of the kidney but is rather for the senior student or practitioner, who is assumed to have a certain familiarity with such clinical conditions as edema, high blood pressure and albuminuria and to have seen cases of nephritis in the hospital wards or in private practice.

In line with the modern tendency to simplify rather than to expand the classification of renal disease, the author considers the major types of nephritis under three headings: acute nephritis, subacute nephritis and nephrosis (discussed together), and chronic nephritis. He justifies his discussion of subacute nephritis and nephrosis together on the grounds that the former has all the symptoms and signs found in the latter, with the addition of certain others, and that it is inconceivable that the albuminuria in nephrosis can occur merely as the result of tubular degeneration. He concludes that it is due to an increase in venous pressure. It therefore may be looked on as a variety of subacute nephritis in which some of the clinical signs are minimal or lacking. He admits, however, that distinctions between "subacute nephritis," "nephrosis" and "lipoid nephrosis," if used in a reserved way, are useful and instructive.

Additional chapters are devoted to the structure and function of the kidney; the renal function in disease; the blood and urine in diseases of the kidney, with a brief consideration of tests of renal function; the classification of nephritis; the "pregnancy kidney" and eclampsia; uremia; renal dwarfism and polycystic kidney; essential hypertension and nephrosclerosis; embolism, poisons and surgical disorders as special causes of renal insufficiency; bacterial infections of the kidney (including a few pages on the use of ketogenic diets for bacilluria; he commends this method of treatment, which promises to displace all others in suitable cases); albuminuria without nephritis, and methods of examination of blood and urine.

So far as possible, the author explains the clinical observations and chemical alterations on the basis of the pathologic changes peculiar to the type of disease under discussion. When no conclusive statement can be given, an attempt is made to review briefly the opposing theories. The treatment of each type of nephritis is outlined; this includes diet and its indications and contraindications, and the newer mercurial diuretics. At the end of each chapter of clinical description, a synopsis of three or four representative cases is briefly appended. The bibliography is brief but adequate for the purposes of such a text. While the author expresses some original opinions on the relationship between certain clinical and pathologic features, he has summarized concisely the theses of others and reviewed what the practitioner should know regarding the function of normal and diseased kidneys, in order to treat his patients in the most accepted manner. The result is a useful and acceptable handbook.

Psychopathology: A Survey of Modern Approaches. By J. Ernest Nicole, L.M.S.S.A., D.P.M.R.C.P. & S., Senior Assistant Medical Officer, Lancashire County Mental Hospital, Winwick. With foreword by W. H. B. Stoddart, M.D., B.S., F.R.C.P. Second edition. Cloth. Price, \$4.75. Pp. 283. Baltimore: William Wood & Company, 1934.

This book has been well received in its first edition. It is a relatively brief summary of all the schools of modern research and thought that have a bearing on psychopathology. It is intended (1) to be a reference book that will give a survey of the conception and views of the different schools, (2) to show where some of the different lines of thought approximate one another, and (3) to indicate the directions in which further reading might be profitable. It accomplishes its purpose but, to a greater extent than any other book of a similar type, brings together many strange bed fellows. Psychiatric treat-

ment, like surgical treatment, offers various avenues of attack on the various disease processes. Unlike surgery, the operation of choice in psychiatry is seldom clearly indicated, for the evaluation of a pathologic process in a mental disease is seldom made on the same basis by any two psychologists. The present volume reduces all the cults and schools of psychopathology to a dead level. The Freudian school, which is growing more and more dominant in this country, is given no more emphasis than Berman's chauvinistic gland theories. Nicole stresses adlerian psychology, which in England has a firmly established place, no more than behaviorism, which, after all, is not a school of psychopathology but merely a technic of studying mental reactions. If, however, one remembers that the scope of this book is vast, one realizes that the author approximates his purpose by including chapters, short it is true, dealing with almost every leading school of psychologic and psychiatric thought of today. The physique theory of Kretschmer, the chemical theories, the social-psychiatric schools of Malinowski and Rivers, the purely psychologic schools of McDougall, Spearman and Watson, are dealt with in order to round out discussions of the work of Jung, Adler and Freud and their disciples. No criticism can be made of the accuracy and validity of Nicole's summaries. To the beginner in psychopathologic work the book may be strongly recommended as a stimulant and guide post for further studies; to the experienced psychiatrist it may reveal some approaches that had not previously been called to his attention.

A Student's Handbook of Clinical Electrocardiography. By William Evans, M.D., M.R.C.P., Assistant Physician and Assistant Director of the Medical Unit, London Hospital. Cloth. Price, 3s. Pp. 49, with 64 illustrations. London: H. K. Lewis & Company, Ltd., 1934.

This small volume consists of a collection of sixty-four electrocardiograms, each being accompanied by a brief explanatory note and a diagnosis. The book is well made, the illustrations are good and the text is simple, but the field for such a volume will be limited, as there are a sufficient number of good works on the subject, several being almost as concise as this one. Its greatest field of usefulness will probably be among interns and those who wish to acquaint themselves merely with interpretation of simple electrocardiograms.

Fases biológicas de la mujer (cartas a Paloma): Pubertad, noviazgo, boda, embarazo, parto, puerperio, crianza, aborto, esterilidad, completo de maternidad, procreación consciente, edad crítica, menopausia. Por Francisco Haro. Paper. Price, 5 pesetas. Pp. 230. Madrid: Javier Morata, 1934.

This book is presented in the form of personal letters from the author to an imaginary daughter or young friend and deals with puberty, love, marriage, pregnancy, labor, the puerperium, nursing, abortion, sterility, maternity, the maternal instinct of women, the critical age and the menopause. The object of the book is to present women in any social stratum of life and at any age with a book of consultation and of teachings on the biologic aspects of woman's life.

Modern Advances in Diseases of the Throat. By Arthur Miller, F.R.C.S., D.L.O., Surgeon for Diseases of the Ear, Nose and Throat, French Hospital, London. Cloth. Price, 10/6. Pp. 120, with 43 illustrations. London: H. K. Lewis & Company, Ltd., 1934.

In this booklet the author attempts to summarize current views on some of the important phases of diseases of the throat. Most of the space is taken up with the tonsil question, and Kaiser's material is freely drawn on in this connection. The chapters on anatomy, physiology and bacteriology of the tonsils are rather brief, while those on indications, complications and end results of tonsillectomy are somewhat more comprehensive. Here and there one finds interesting paragraphs on such topics as tonsillectomy in diabetic patients, tonsillectomy in singers and removal of the tonsils by diathermy. The remainder of the book is taken up with a sketchy review of the adenoids and brief discussion of some of the more common inflammatory processes in the throat. On the subject of neoplasms a few pages are devoted to malignant conditions of the tonsils and palate. The book is hardly thorough enough for the specialist but may well be recommended for the general practitioner. The text is clear, the illustrations are adequate and the bibliography is valuable to those who wish for further details.

Medicolegal

Accident Insurance: Typhoid Carrier Not "Totally and Permanently Disabled."—The defendant insurance company issued a policy to the plaintiff, a dairy farmer, which provided certain benefits if he should become totally and permanently disabled, either physically or mentally, from any cause whatever, to such an extent as to render him wholly, continuously and permanently unable to engage in any gainful occupation. While the policy was in force, the state commissioner of health declared the plaintiff to be a typhoid carrier, permanently quarantined him from all connection with the production or sale of milk or of any other food product, and excluded him from his own dairy farm. Because he was a typhoid carrier, the plaintiff could not obtain work. He sought compensation from the insurance company on the ground that he was totally and permanently disabled, the insurance company denied liability, and he sued on the policy. The trial court dismissed the complaint and he appealed to the supreme court, appellate division, fourth department, New York.

The rights of parties to an insurance policy, said the supreme court, must be determined by the policy itself. In construing the total disability provisions of this policy, this court must give effect to what would be ordinary lay interpretation. Can it be said that, when this policy was written, the parties had in mind that a typhoid carrier, affected in no other manner, was physically disabled? Would the ordinary business man in making one of his customary contracts ever consider a typhoid carrier as physically unable to work? A carrier does not have typhoid fever; he is not ill; he simply harbors bacilli and excretes them; his strength is not impaired; his constitution is in no way weakened or undermined; he has the same capacity for labor which he always had; his mental powers are not affected; he suffers no pain or impairment; he would never know that he was a carrier if fecal or urine specimens were not submitted for laboratory examination. His inability to get work is not due to any physical impairment but to the edict of the state, or to fear of infection on the part of others. As the insured concedes in his brief, the carrier state in and of itself, if the carrier's duty to the public and the law of the state be disregarded, would not prevent him from milking cows and handling milk. Physically he is fully able to continue the manual tasks associated with the dairy business. His disability is social in its nature, rather than physical. While it is true that he has found himself unable to earn a livelihood, his inability is not caused by physical impairment of his body, and he is not physically disabled within the meaning of the policy.

The supreme court accordingly affirmed the judgment of the trial court dismissing the plaintiff's complaint.—*Gates v. Prudential Ins. Co. of America (N. Y.)*, 270 N. Y. S. 282.

Malpractice: Contemporaneous Tonsillectomy and Extraction of Teeth.—Hughes was suffering from rheumatism and chronic myocarditis. His physician advised the removal of his tonsils and an x-ray examination of his teeth, which examination was made by the defendant Brown, a dentist. The defendant Desmond, a physician, was then called in and advised the removal of the tonsils and the extraction of at least some of the teeth while the patient was under the anesthetic for the tonsillectomy. The defendant physician performed the tonsillectomy, and the defendant dentist extracted some infected teeth, but only sixteen of them, although the patient had insisted on the extraction of all his teeth. The patient died one week later. Contending that it was improper, in view of the patient's condition, to remove the tonsils and so many teeth at one time, his widow sued the defendant-physician and dentist. A verdict was given for the plaintiff and the defendants appealed to the Supreme Court of Colorado.

All that was required of the physician and dentist, said the Supreme Court, in this case, in diagnosing and treating their patient, was such a degree of skill and care as was ordinarily possessed by those in the practice of their respective professions, under similar circumstances and in their particular locality. Whether or not these requirements are met can

usually be determined only from the opinions of witnesses learned in the corresponding professions. There is no actionable violation of a duty when only the best judgment, under the circumstances of the case, is required and is used. The burden is on the plaintiff to establish negligence. The evidence here shows that the defendants possessed ordinary and reasonable learning and skill in their professions and that the practice they followed had been successful in similar cases. The plaintiff called several expert witnesses, some of whom said that they would not have pulled more than two or three teeth but the majority of whom testified that such matters were to be left to the best judgment of the operator. The defendants called many experts, who testified, in substance, that operations similar to those performed in this case are advisable under like or similar circumstances and many times are followed with desirable results. Who can say with certainty that the defendants abandoned the field of accepted practice? There must be a clearer case of total abandon than here appears before liability occurs, otherwise the learned judgment of the skilled professions of medicine and dentistry would be lost to the human race.

Further, said the Supreme Court, the burden was on the plaintiff to show that the acts of the defendants were the direct cause of death. No such evidence was produced. The fact that there is a lamentable result does not of itself satisfy that burden imposed on the plaintiff. The burden is not met by showing that death might have resulted from the operation complained of, and it is improper to allow jurors to conjecture as to the efficient and proximate cause. The possibility of death as the result of such operations is not sufficient; there must be evidence eliminating the intervention of other causes which might exist.

For the reasons stated, the judgment in favor of the plaintiff was reversed.—*Brown v. Hughes (Colo.)*, 30 P. (2d) 259.

The Care of the Joints in Chronic Proliferative Arthritis of Children

DRS. FRANK R. OBER and WILLIAM T. GREEN, Boston: In any disease in which the etiology is unknown, the treatment must be symptomatic or directed toward the general or local manifestations of the disease. Proliferative (atrophic) arthritis is no exception to this rule. After the adoption of general measures that improve the health and nutrition of the patient and empirically seem to be helpful, and removal of definite focal infection at least for its general effect, there remains the local care of the joints. In our opinion the latter, the proper care of the joints themselves, is 60 per cent of the therapy in proliferative arthritis of children. The joints should hold one's interest from the very beginning of the disease.

The changes that occur in proliferative arthritis are due not only to the disease directly but also to muscle spasm and

inactivity in a position of deformity. Muscle spasm, nature's way of immobilizing a joint, forces the cartilaginous surfaces together and cannot but increase injury to the joint surfaces. Trauma increases the inflammatory reaction and the spasm of the muscles. Therefore the first principle of therapy in the acute stages of the disease is rest and the avoidance of all trauma; this presupposes freedom from weight bearing and some degree of immobilization. However, motion is necessary even in a normal joint to preserve its integrity. The second consideration, then, in the care of the joints, is the prevention of those changes that are the result of disuse. This implies not only prevention of deformity but performance of active motions, to minimize nutritional changes in the joints and also to decrease atrophy of bones and muscles. The general nourishment of these children is nearly always below par. Some of them look as if they had celiac disease. With a large number there is recession of the lower jaw. A diet high in vitamins is prescribed, including yeast, fresh fruits, green vegetables and meat, with reduction but not elimination of carbohydrates.

The problem, then, is to rest the joints and prevent deformity, eliminate all trauma, control muscle spasm, and yet keep the joints moving. It is of importance to educate the mothers of the patients. The measures found to be most useful in the prevention of deformities include periods of rest and fixation, periods of traction, the use of pulleys that can be managed by the patient himself, periods of exercise in a pool with water at 96 F., special exercises for quadriceps, gluteal and abdominal muscles, and crocheting and other types of occupational therapy.

We should like to emphasize (1) the value of counterpoised motion in allaying muscle spasm and developing motion of the joints in proliferative arthritis of children and (2) the fact that hit or miss physical therapy, with only a vague purpose in mind, is not the solution. These may be helpful, but the primary measures are well planned active exercises, which must be carried out frequently and regularly by some one who spends a great part of the time with the patient, in the usual instance, the mother, who is carefully trained and supervised.

The Management of Atrophic Arthritis

DRS. W. P. HOLBROOK and DONALD F. HILL, Tucson, Ariz.: Insufficient attention has been paid to the variations of management necessary during the different phases of atrophic arthritis. Many good therapeutic aids have not only been used unwisely but often discarded because they were used at the wrong time. The course of atrophic arthritis may vary from a rapidly progressing, febrile and exceedingly severe illness, in which the patient becomes helpless almost immediately, to an afebrile illness with little discomfort over a period of years but which may just as certainly go on to a crippling deformity. Because of these wide variations in onset and course it seems advisable to consider the therapeutic measures in relation to the stage of the disease.

Our conception of atrophic arthritis does not admit a known, single specific etiologic agent, or specific cure. We have previously reported carefully controlled experiments with various types of therapy. These consisted of placing about 400 patients with atrophic arthritis on a program that included diet and bowel management, prevention and correction of deformity, rest, exercise, general physical therapy, and proper climatic conditions. After a control period of several months 100 patients had foci removed, 100 were given blood transfusions, 100 were treated with vaccine, and 100 were given special heliotherapy. Progress was observed over periods ranging from months to years. The results of this study emphasized the nonspecificity of any single therapeutic agent used.

Our present program of treatment includes the following measures: The early establishment of a correct routine of living. This may mean partial or total elimination of business or domestic responsibilities, avoidance of conditions producing nervous strain, and establishment of regular hours. The amount of rest and general activity depends entirely on the severity or phase of the disease process, and the latter should be pushed to tolerance, which may roughly be determined by the presence of increasing fatigue or pain that persists during rest after exercise. The patient may be guided by the rule that pain during exercise is of little or no significance, provided it does not continue after exercise. Proper sedatives are used for

nervousness and to insure adequate sleep. Local heat, splints and acetylsalicylic acid are helpful. Corrective exercises, occupational therapy and avoidance of painful postures are indicated. As most patients with atrophic arthritis are undernourished we favor a diet high in calories and vitamins with plenty of red meat, starches, fresh fruits and green vegetables, and the use of yeast, wheat germs and cod liver oil. Belladonna, dilute hydrochloric acid and insulin are sometimes prescribed. When the weight is normal, a diet low in starch and high in vitamins may be used. If obesity is present a diet low in starch and low in fat is prescribed. To regulate elimination, liquid petrolatum, agar, oil-retention enemas and glycerin suppositories generally suffice. High enemas or colonic irrigations are of questionable value.

The various accepted measures for the correction and prevention of deformity must be used as necessary: physical therapy, splints, specific exercise and supports. Before removing foci, we favor a preliminary period of constitutional treatment to avoid acute exacerbations following focal removal. Preoperative transfusions are frequently used, and the removal of foci is generally avoided in the acute phases of the disease. Vaccines have only occasionally proved of undoubted merit. We favor the intravenous use of minute doses of antigen to which the patient is strongly skin sensitive. A series of small blood transfusions often occasions marked relief for patients with acute or subacute arthritis; they seem of little help in chronic afebrile cases.

At the proper time and in proper amounts, heliotherapy may be most useful, and the climatic advantages of Arizona seem definite. It must be understood, however, that without a proper routine of living, arthritis, even on the Tucson desert, can continue as a sad and crippling disease. Too many people come to the Southwest believing that climate performs miracles.

DISCUSSION ON PAPERS OF DRS. SLADEN, ENSIGN AND MCCOLL, DRS. OBER AND GREEN, AND DRS. HOLBROOK AND HILL

DR. ROBERT B. OSGOOD, Boston: Attention should be called to the great disparity in the ratio between the 128 cases of hypertrophic arthritis and ten cases of atrophic arthritis of Drs. Sladen, Ensign and McColl. I have been inclined to believe that the influence of diet was greater in the atrophic than in the hypertrophic type, and that the matter of quality was more important than quantity. This study suggests that quantity is important, especially the lack of what they properly call "protective foodstuffs," which most physicians speak of as vitamins. A lack of the protective foods in effect constitutes a deficiency diet. What Minot has spoken of as an "optimum diet" is still of great importance in the treatment of chronic arthritis, and most earnest attempts should be made to determine what constitutes such an optimum diet, not for both types or even for one or the other type, but for each individual who is suffering from the disease. It would seem wise not to attempt any rigid standardization of diet but to study the alimentary aberrations of each patient and strive to meet their individual needs of both optimum intake and efficient outgo. Drs. Ober and Green's paper and moving pictures speak for themselves. Prevention of deformity is of supreme importance. This means not just the routine use of physical therapy but the use of measures especially designed and persistently carried out not only to prevent deformity but also to retain and increase joint mobility and improve joint circulation. This is not, I am sorry to say, what physical therapy means to the average physician. Physical therapy is one of the most effective weapons against eventual restriction of function in the atrophic type of arthritis. Of course this presupposes that the generalized disease is being attacked by all other weapons, such as rest, fresh air, sunlight, diet, and the removal of sources of infection. I do not quite agree with Drs. Holbrook and Hill when they say that "regardless of treatment there are recurring periods of exacerbation and remission." I agree that periods of exacerbation and remission often occur in spite of treatment, but not all patients go through these periods, nor is such periodicity regular. When therapy becomes more intelligent, and mental and physical extraneous conditions can be controlled, it will not be necessary to consider such exacerbations as inevitable. In connection with the management of the

bowels, they might well have mentioned abdominal massage after the Drown method and Hugh Owen Thomas's cure for constipation. This consists in making the foot of the bed 6 inches higher than the head, whereby posited and kinked intestines crowded into the pelvis may be given more room to function during the night of recumbent relaxation. These mechanical measures I have found to be strong adjuvants in improving alimentation. I agree with the authors' views as to the removal of foci of infection and the employment of vaccines. When the attitude of clinicians in general toward chronic arthritis becomes as sane as that of Drs. Holbrook and Hill, it seems reasonable to hope for fewer tragedies and more successes in the management of the different phases of chronic atrophic arthritis.

The Relation of Dietetics to the Reduction of Tissue Swelling in Arthritis

DRS. C. W. SCULL and RALPH PEMBERTON, Philadelphia: A certain amount of swelling of tissue is an accompaniment of chronic arthritis, and the results of successful therapy include reduction of this swelling as well as of pain and stiffness in joints. This study concerns itself with the influence of diet and postural therapy on such swelling of soft tissues, to be noted especially on the dorsum of the hands. The rapidity with which this swelling is at times reduced suggests that it represents an accumulation of fluid. Since adequate methods for the direct determination of this possibility are not available, the use of indirect methods is necessary; namely, a study of water balance during the interval when swelling is subsiding.

Approximate determinations of water balance indicate that the convalescing arthritic patient experiences a net loss of water from the body. Several factors may be responsible, among them the recumbent position of hospital patients and the effect of diet. On standing, blood becomes concentrated; during recumbency, water is transferred from tissues to the circulating blood. The specific gravity of the venous blood of standing patients averaged 1.028, as compared to 1.026 during recumbency. Such a change is indicative of a transfer of water from tissues to blood in the latter position.

Dehydration and reduction of soft tissue swelling can be demonstrated during the use of submaintenance diets. Calculations indicated to us that tissue catabolism did not account for the amount of water lost, and it was concluded that this loss was of pathologic, not physiologic, fluid. We believe that the benefits frequently resulting from the use of diets low in calories and carbohydrates may thus in part be explained. Such benefits accrue to patients both with atrophic and with hypertrophic arthritis, and the restriction of such therapy to just one type seems at present unwarranted. We believe that disturbances in the distribution of water in tissue may represent a significant pathologic deviation in the rheumatoid syndrome and that the diets used tend to correct such disturbances. The more drastic methods of dehydration, such as by vigorous sweating, purgation and diuresis, have proved of little value and may be dangerous. The more sustained and "physiologic" method of dehydration by suitable diets is preferred.

DISCUSSION

DR. A. ALMON FLETCHER, Toronto: The symptoms of an arthritic patient may change abruptly following a number of events: atmospheric change, removal of foci, use of vaccines and so on. A patient will experience marked stiffness and pain, with increase of swelling noted on arising in the morning. A few hours later he is much better. A varying edema of tissue has been considered a possible cause of morning stiffness. It is interesting to learn that Drs. Pemberton and Scull have noted abrupt improvement, with shifts in water balance and metabolism under the influence of diets low in calories. One must, however, be careful in the application of such observations, as physicians in general are apt to resort to one favorite method of treatment and may be led to use submaintenance diets to the exclusion of other useful therapeutic measures. Patients with arthritis are suffering with a chronic disease due to a variety of factors. All measures calculated to overcome these various factors must be used, and the sentiment of patients and physicians to use one measure, such as a diet, to the exclusion of others, should be combated, for diets alone may be ineffective.

DR. F. J. SLADEN, Detroit: Fearful of the possible harm that might result from the use of starvation periods, such as advocated by Dr. Pemberton as a preliminary measure to further treatment by diet of patients with severe arthritis, I have considered them justified only in relative emergencies, when nothing else has helped. Although I have never understood why, I have had very satisfactory results when I have tried them. I am interested in the explanation suggested now by Drs. Scull and Pemberton. However, I believe there must be a more profound factor at work that hasn't yet been discovered.

DR. RALPH PEMBERTON, Philadelphia: I welcome Dr. Sladen's comment that care must be taken in prescribing submaintenance diets in these cases. There are definite dangers inherent in undernutrition as there are in many of the other measures used for arthritis. Our laboratory work is of an academic nature chiefly, an attempt to study some of the physiologic factors underlying the production and reduction of swelling. I know of no way to explain the presence of this tissue swelling. It may be an inflammatory exudate, although it is difficult for me to interpret it as such.

DR. WALTER BAUER, Boston: From the data presented, one is not justified in drawing any final conclusions concerning the water balance. Not until one actually determines the total acid-base metabolism and insensible perspiration throughout the experimental period can one state with certainty whether there has been an actual loss or gain of water.

DR. C. W. SCULL, Philadelphia: These patients were subjected to a fairly constant regimen, so that there was little likelihood of increasing or changing the sensible loss from day to day. We therefore considered that it represented a constant. We included observations on acid-base balance. We admit that these experiments are somewhat preliminary in nature.

The Peripheral Blood Circulation in Chronic Arthritis and the Influence of Vasodilators

DR. JOSEPH KOVACS, New York: Defective peripheral circulation and disturbed blood supply to affected joints are apparent in many cases of chronic arthritis. Questions arise as to which part of the peripheral circulation (larger arteries, veins, capillaries) is disturbed in chronic arthritis and which disturbances can be considered etiologic factors or merely aggravating agents. Although ligation of arteries to the patella of animals results in changes similar to hypertrophic arthritis, in man the obliteration of major vessels has a more destructive effect on soft tissue and does not produce arthritis, as witness the absence of the latter in endarteritis obliterans. Varicose veins present in many cases of arthritis have an aggravating, not an etiologic, rôle. Phlebitis likewise is a complication, not a cause, of rheumatic infection.

In arthritis, disturbances of peripheral circulation involve chiefly the minute vessels. In cases of atrophic arthritis I found small constricted capillaries in 53 per cent, a slow blood flow in 65 per cent, and a decreased number of capillaries in nailbeds peripheral to joints with definite swellings. In hypertrophic arthritis I found small capillaries in 28 per cent of cases, a slow blood flow in 53 per cent, and decreased number of capillaries near Heberden's nodes. Subnormal skin temperatures were found in 53 per cent of the combined types. Although I am not certain that articular vessels are similarly affected, a similarity in state possibly may be rightly assumed.

The use of vasodilating drugs to increase peripheral circulation, therefore, seems indicated. The oral use of cholin compounds, histamine and nitrites is ineffective, and they produce only brief dilatation when administered subcutaneously. I have studied the effects of iontophoresis, the introduction of drugs through the skin by means of the polar effect of the galvanic (direct) current. Others have found histamine iontophoresis helpful in muscular rheumatism, unsatisfactory in chronic arthritis. Acetylcholine is rapidly destroyed by body fluids and blood. The new compound acetyl-beta-methylcholine chloride (mecholin) is preferable, as it is more potent, more stable and less toxic. The local and general effects of iontophoresis with mecholin have been compared to those with histamine. Locally, mecholin acts mostly on arterioles and produces an increased

skin temperature for from two to eight hours, increased sweating for from four to ten hours, transitory "goose-flesh," an increased oscillometric reading, a faster capillary flow, and a slight increase in the local leukocyte count. I have treated fifty-two patients with chronic arthritis, thirty with the atrophic type and twenty-two with the hypertrophic type. Definite improvement resulted in 90 per cent of the cases of atrophic arthritis, including stubborn cases, and in 80 per cent of those of hypertrophic arthritis. In the latter group, however, similar benefits resulted from other and more usual measures. Reduction of joint swellings and an increased capillary flow were features of the result. Iontophoresis is contraindicated for febrile patients and in the presence of asthma, cardiac disease and advanced senility. Further investigation is needed to determine the amounts of these drugs absorbed during iontophoresis and their mode of action. Experiments indicate that the effects are specific and not simple galvanic effects.

DISCUSSION

DR. PHILIP S. HENCH, Rochester, Minn.: Dr. Kovacs contends that there are significant alterations in capillary blood flow in both atrophic and hypertrophic arthritis, that these alterations may be of etiologic importance, and that most patients are materially improved when these alterations are corrected, at least in part. I agree that arthritis is not primarily associated with occlusive vascular disease of large vessels. I have never seen a related arthritis among a large number of cases of thrombo-angiitis obliterans. In a number of rheumatic diseases, pathologic changes are found in small vessels. In chronic atrophic arthritis, there are often very obvious alterations in general blood flow: low blood pressure, cold clammy extremities, and lowered skin temperature. Dr. Kovacs and others anticipate finding constricted capillaries in the nailbeds of the arthritic patient. At the clinic, Dr. George Brown, Miss Roth and I have studied the capillary flow in a large number of cases of atrophic and hypertrophic arthritis. Like Prusik, we have been unable to find consistent alterations. In many cases the size of the capillaries is unaffected, or slightly dilated, but not constricted. Often, however, flow is slow. Some arthritic patients exhibit vasomotor alterations long before the onset of their joint symptoms. In others they develop fairly early in the course of the disease. Many severe cases exhibit them rather late. The fact remains that the alterations are not consistently present and, during the past five years, while selecting cases suitable for sympathectomy, we have seen many patients with marked, even advanced, arthritis with warm extremities and without changes in capillary size or flow. Dr. Kovacs himself finds changes in only about half the cases of atrophic and in only about a fourth of those of hypertrophic arthritis. It has been an attractive idea that arthritis is the result of "blood hunger," that the changes in joints are secondary to an inadequate supply of blood. One must distinguish between atrophic and hypertrophic arthritis. Recall that when patellar vessels are ligated and the blood supply is sharply diminished, resulting alterations in bone are chiefly hypertrophic, not atrophic. This is what one should expect if one accepts the recent dictum of Jones and Roberts that bone undergoes increased calcification if its blood supply is decreased. However, it undergoes decalcification if its blood supply is increased. If this is true, one might better search for an augmented, not a decreased, blood supply to account for bone atrophy in atrophic arthritis, and indeed such a state has been suggested as being present in the form of hyperemia and the formation of new vessels. Raynaud's disease presents an outstanding example of diminished blood supply from vasospasm. If vasoconstriction is the cause of arthritis, isn't it strange that arthritis occurs in less than 5 per cent of cases of Raynaud's disease? Since vasomotor changes are so inconsistently present in chronic arthritis, early in one, late in another, and not at all in a third, they must represent not the cause of the disease, not even an essential part of the disease, but a complication appearing at varying times and in varying degrees as the sympathetic nervous system is perhaps variously affected by the "toxins" of the disease. As Dr. Kovacs pointed out, an interpretation of alterations in the capillaries of the nail-bed can be made only with consideration of the age grouping. What is needed even more than this is a study of capillaries correlated to the localization, duration and severity of the disease. I

have not used iontophoresis and cannot discuss its merits. I am sure that Dr. Kovacs will agree that, while iontophoresis may be effective, the ultimate goal is some method of vasodilatation requiring neither the cutting of the sympathetic nerves nor the use of electric machines beyond the financial province of most patients. The work of Starr, and more recently of Goldsmith, indicates that mecholol given orally in much larger doses than Dr. Kovacs used produces fairly prolonged significant vasodilatation. The effects of such doses should be compared to iontophoresis. When I suggest the desirability of vasodilatation I do not necessarily mean capillary vasodilatation; arteriolar vasodilatation is preferable. They are not the same, and I think that too much stress should not be laid on the significance of capillary constriction or capillary vasodilatation used as an infallible criterion of improvement. Skin temperature is dependent on arteriolar, not capillary, tone. Cold, clammy hands signify arteriolar, not necessarily capillary, constriction. Indeed, the capillaries may be dilated although their flow is sluggish. The size of capillaries is relatively unimportant, as their tone is dependent on the state of arteriolar circulation. Fix the arterioles and the capillaries will take care of themselves, as is demonstrated after sympathectomy when, in the presence of arteriolar dilatation and an improved flow, the capillaries are not more, but less, dilated than before operation.

DR. IRVING S. WRIGHT, New York: One of the most interesting observations is that arthritis rarely occurs in cases of occlusive vascular disease. When the obstruction to blood flow to a part is sudden or gross, arthritis is not produced. Occlusive disease of large vessels is not a causative factor in arthritis. Studies on the size and flow of capillaries lead me to feel that capillary alterations are not the cause of arthritis, although frequently they accompany it. At any rate, from studies of surface capillaries and skin temperature it is impossible to draw definite conclusions as to the condition of articular circulation. Dr. Kovacs' revival of an old method of treatment is worthy of careful consideration, and my observations indicate that the effect of these drugs by means of iontophoresis is more prolonged than by the oral or hypodermic route. Dr. Kovacs has made no claim as to the curative value of mecholol iontophoresis, but if it will relieve pain and discomfort it has a rightful place in therapy. In considering the high percentage of results, one must remember that the psychologic effect of a rather elaborate technique may be very definite. Further time and work will be necessary to determine the permanence of its effects.

DR. D. E. KAUFMAN, St. Louis: I have used mecholol in twenty-three cases of chronic arthritis with benefit to the large joints but none to the small joints, such as those of the fingers and wrists. In six cases the knees have been gratifyingly benefited by treatments three times a week.

DR. JOSEPH KOVACS, New York: I agree with Dr. Hench that the impaired capillary circulation cannot be accounted for as an etiologic factor in chronic arthritis. On the other hand, it has been found, in more than half the cases of arthritis, that there is an impaired capillary circulation aggravating the arthritic condition. Relieving it, one surely benefits the patient. The simplest way of medication is oral administration, I admit, but the simplest method is not in every case the most satisfactory one. The large doses administered by Goldsmith seem to me to be quite expensive therapy. The need for these large doses proves that most of the drug is destroyed in the stomach before it is absorbed, and the part that gets in the circulation causes a mild, general vasodilatation. In arthritis one needs primarily to increase the local circulation of the affected joint or joints, and iontophoresis seems to me the most adequate method for accomplishing this. I usually administer treatment twice a week and have had better results on small joints. It increases, first of all, the circulation of the affected joints and produces only a slight, general reaction. I agree with Dr. Wright that further time and work will be necessary to determine the permanence of acetyl-beta-methylcholine chloride iontophoresis. Dr. Kaufman's observations prove only that there is still a large field unexplored, and much more work must be done before the therapeutic effects of acetyl-beta-methylcholine chloride iontophoresis can be fully evaluated.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to *THE JOURNAL* in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Investigation of Patency of Peripheral Arteries—Formijne describes a method for the registration of arterial oscillations in the fingers and the feet, which is used as a test for the patency of the main arteries. By alternative compression of the radial and ulnar arteries on the hand and of the posterior tibial and dorsal pedal arteries on the feet, the composition of the oscillations can be studied. The so called occult blood pressure in the fingers and the big toes was studied by the method of Gaertner. The influence of compression of arteries on the occult blood pressure was studied and used for testing the patency of these arteries. A third method, called the shock method, was used for testing the patency of almost totally occluded arteries. Most of these arteries were found to have some degree of patency. The relation between the results of arterial palpation and the compression method was investigated in different groups of patients.

Chronic Heart Disease and Total Ablation of Thyroid.—Davis and his collaborators present observations concerning the rate and character of changes in the size of the heart in thirty seven patients, and changes in electrocardiographic voltage in thirty-two patients in whom artificial myxedema was produced by total ablation of the normal thyroid. These patients were observed from one and one-half to twelve months after operation. The degree of the hypothyroid state was estimated by measurements of the basal metabolic rate, the velocity of blood flow and the blood cholesterol, and the signs and symptoms of myxedema. Changes in the size of the heart and electrocardiographic voltage were interpreted on the basis of these indexes. After total thyroidectomy, fifteen of twenty-two patients having congestive failure showed an increase of more than 0.5 cm in the transverse cardiac diameter, three showed no change, and four showed a decrease of more than 0.5 cm. Of eleven patients having angina pectoris, eight showed an increase in the size of the heart and three no change, of four patients with no heart disease, three showed an increase in the size of the heart and one no change. The variations in changes in the size of the heart in the patients who had congestive failure before operation were the result of two opposing factors: the effect of the hypothyroid state tending to increase the size of the heart, and the restoration of circulatory compensation tending to decrease its size. Observations on the changes in the electrocardiographic voltage of P and T waves in thirty-two patients gave the following results. Of twenty

patients having congestive failure, fourteen showed a decrease, five no change and one an increase in voltage, of eight patients with angina pectoris, five showed a decrease and three no change in voltage, four patients without heart disease all showed a decrease in voltage. The rate and extent of increase in the size of the heart and of decrease in electrocardiographic voltage of these patients paralleled the development of the hypothyroid state and were a manifestation rather than a secondary consequence of myxedema. These changes generally showed no progression when the metabolism was fixed at a given decreased level by thyroid medication and regressed if the metabolism was raised significantly. In spite of these changes in heart size and electrocardiogram, the patients studied showed a disappearance of signs and symptoms of congestive failure or of angina pectoris with persistence of improvement from three to twelve months and an increased capacity for work as measured by standard exercise tolerance tests. "Myxedema heart" in the sense of a condition aggravating or precipitating attacks of congestive failure or angina pectoris does not develop when hypothyroidism is produced by total ablation of the normal thyroid in patients whose metabolism is maintained at about minus 30 per cent.

Areas of Ventricular Deflections in Electrocardiogram.—Wilson and his associates state that by measuring the areas of the ventricular deflections of the electrocardiogram it is possible to determine the mean electrical axis of QRS, which gives the direction in which the excitatory process spreads over the average element of ventricular muscle, and the mean electrical axis of T, which gives the inverse of the direction in which the recovery process spreads over the average element of ventricular muscle. If all the ventricular muscle passed through the period of excitation at the same time and in the same way, the area of QRS and the area of T would be equal in absolute magnitude but opposite in sign, and the area of QRST would be zero. The area of QRST is a measure of the electrical effects produced by local variations in the excitatory process. The mean electrical axis of QRST gives the direction of the line along which these local variations are greatest. The local variations in the excitatory process that determines the mean electrical axis of QRST are dependent on factors that act on different parts of the ventricular muscle with different intensities. They are not materially influenced by the course of the excitatory process over the ventricular muscle.

Etiology of Mongolism—Rosanoff and Handy summarize fifty-nine cases of mongolism in twins and report five new cases. In utilizing this material in their study of the etiology of mongolism they find that the etiologic factors are narrowed down to those that must be at work in the germinal or early embryonic period of environment. There is definite statistical correlation between the incidence of mongolism and the age of the parents. An attempt is made here to show, however, that the real etiologic factor is the age of the mother, that of the father having only an indirect bearing by reason of being in statistical correlation with the age of the mother. Similarly the size of the family, the order of birth, "uterine exhaustion," and so on, play no part in the etiology of mon-

golis; they stand out in the statistics only by reason of their correlation with the one real factor: the age of the mother. Mongolism is more common among boys than among girls. This finding is so constant as to force one to assume that, although injury to the ovum is the essential cause of mongolism, the spermatozoon is not without its influence. The X-chromosome in the female-producing spermatozoon seems in some cases to have the power of protecting an injured ovum against its tendency to develop into a mongolian child. It is pointed out in this connection that mongolism varies greatly in the severity of its manifestations and, on the whole, is milder in girls than in boys, possibly owing to partial protection by the additional X-chromosome. All the known facts concerning mongolism seem to point to some condition of the ovary as underlying its pathogenesis. No systematic pathologic investigation of the ovaries of women who have given birth to mongolian idiots has been made, to the authors' knowledge. Coarse or diffuse lesions seem to be excluded as a possible cause. All available evidence seems to justify the speculation that foci of tissue change—perhaps scars—marking the sites of old ovulation are the cause of the trouble.

Cutaneous Reactions to Vaccines.—De Bruin and Vedder observed that infants younger than 3 months react weakly or not at all to intracutaneous injections of vaccines of dead pneumococci and streptococci. Older infants and young children react in a gradually increasing percentage of cases. No type specific or species specific differences between the vaccines were observed. Vaccines of pneumococci and green producing and hemolytic streptococci act the same. The reaction is specific for the group of pneumococci and streptococci. Children who have suffered from bronchitis, lobular pneumonia and other conditions in which pneumococci and streptococci are of etiologic importance often give a positive reaction; other children, a negative reaction. Possibly as a result of such a condition, a negative reaction changes into a positive one. Older children and adults (students) in the majority of cases react positively. Children who have suffered from lobar pneumonia, acute rheumatic fever and chorea almost never react to the vaccines. In persons having suffered from erysipelas the percentage incidence of negative reactions is the same as the chance of recurrence. In erysipelas a positive reaction points to immunity; a negative one indicates that a chance of recurrence exists. In lobar pneumonia and rheumatic fever also some relation exists perhaps between a negative reaction and the incidence of recrudescence. The skin reaction has a significance analogous to the tests of Pirquet and Mantoux.

Repeated Sedimentation Tests.—Van Antwerp points out that the fact that sedimentation rates in children show an unexplained tendency to vary widely without intervening clinical causes should be of value to pediatricians, regardless of the cause. That this occurs commonly is demonstrated by the fact that 27 per cent of his patients gave readings erroneous enough to mislead in their interpretation. His experience, however, shows that a repeated test will usually give the correct reading. Occasionally a repeated test will show a persistently high rate, though this is not common. In such an event, careful clinical search should satisfy one as to the presence or absence of any condition warranting a high rate. A persistently high rate need serve, therefore, only as a warning of the possibility of the presence of a pathologic condition; it need not be held as conclusive. The author performs two sedimentation tests on successive days on all newly admitted patients, the lower rate being taken as the one reflecting the presence or absence of a destructive lesion. He believes that apprehension on the part of the patient is a factor in erroneous results in sedimentation tests, though he has not thus far been able to prove it. If such is the case, it will be necessary to repeat tests on patients giving a high rate, as basal metabolic tests are now repeated. It is already well known that certain types of insanity are characterized by high rates of sedimentation and it is interesting to consider the possibility that the factor influencing the rate in this class of patients may be that of apprehension, because of emotional instability. Later observations comparing blood sugar content with rates of sedimentation will be offered as a factor of proof or disproof of the contention that apprehension influences the rate of sedimentation.

Pulmonary Embolism in Trauma.—Vance discusses the incidence of pulmonary embolism in the traumatic cases and what factors tend to produce the complication. A detailed examination of sixty post-traumatic cases of pulmonary embolism disclosed the following facts: 1. The sex incidence showed that thirty-seven were women and twenty-three men. 2. The age incidence indicated that 50 per cent of the cases occurred between the ages of 40 and 60 years. 3. The types of trauma that injured the patients were the ordinary casualties encountered in any large city. The lesions varied in severity from severe fractures of the pelvis or of the shaft of the femur to mere contusions and abrasions of the extremities. 4. The interval that elapsed between the onset of the trauma and the sudden death by pulmonary embolism varied between four days for

the minimum and fifty-four days for the maximum. 5. When the trauma involved the bones and soft parts of one of the lower extremities, thrombosis was found in the veins of the corresponding lower extremity in thirty-two instances. In fourteen cases of this type a thrombus could not be found. In nine cases, thromboses of the femoral vein were found. A traumatic lesion near the femoral vein or its tributaries has an influence on the production of thrombosis in that vein. In addition, femoral vein thromboses and fatal pulmonary embolism occurred in nontraumatic cases of all sorts, so that the basic etiology of this condition is some factor besides physical injury. 6. Microscopic investigation of the thrombosed veins of the lower extremity, both in the traumatic and in the nontraumatic cases, disclosed that in almost all instances there was a phlebosclerosis, a subacute phlebitis or a periphlebitis of greater or lesser degree. In many cases these lesions probably antedated the trauma. In others the effects of the trauma, whether general or local, probably precipitated the inflammation and produced a nonseptic thrombosis, which resulted eventually in a fatal pulmonary embolism. 7. In seventeen of twenty-one cases which the author examined personally, various acute and chronic disease conditions were present, which may have contributed to the formation of the thrombosis in the veins of the lower extremity.

Traumatic Peptic Ulcer.—Eusterman and Mayo believe that there is apparently adequate evidence to justify the contention that under exceptional circumstances a chronic ulcer of the stomach can have its origin in external, nonpenetrating trauma to the epigastric region. In one case, fairly characteristic symptoms of a hemorrhagic gastric ulcer developed following a severe blow to the left epigastric region. Roentgenoscopy confirmed the presence of a penetrating ulcer near the lesser curvature five months after the injury. Following hospitalization and intensive medical treatment, the lesion disappeared completely and clinical cure resulted. In any case in which a plaintiff claims that a gastric or duodenal ulcer followed external trauma, the physician whose opinion is sought should see that the four postulates of Liniger and Molineux are satisfied. A second cause of ulcer is chronic trauma from within. The commonest form of ulcer of this nature is that secondary to congenital (nontraumatic) diaphragmatic hernia; foreign bodies in the stomach may also cause ulcer. Such secondary lesions are not indurated as a rule and all tend to heal readily following reduction of the hernia or removal of the foreign body.

Puerperal Infection.—Martland believes that the problem of puerperal infection is almost entirely anatomic, depending on anatomic pathways for its spread, on physical and mechanical phenomena of stasis, on drainage and on cellular reactions called forth for defense, and that it has little to do with fancy theories of immunity and selective affinity of certain strains of bacteria for certain tissues. In addition, the condition of septicemia, which denotes only the ability to recognize bacteria in the circulating blood, is in many of these cases intermittent and at times does not exist. In other words, bacteria do not multiply and grow in the blood but are discharged into it from primary, secondary or tertiary depots in the various organs, usually in an intermittent fashion. When they are thrown into the circulating blood, nature makes every effort to rid the blood quickly of their presence through its organs of elimination and filtration. The application of chemotherapy in the intravenous injections of mercurochrome, gentian violet and other like substances is excusable only on the premise of attempting to kill those organisms circulating in the blood at the time of the injections and thus prevent the establishment of secondary foci in other parts of the body. Medication is, then, of no avail; vaccines and serums are equally useless. Only supportive blood transfusions seem to be of any benefit. The more radical the treatment, the higher the mortality. The best results are obtained by those who do the least. While the anatomic view of the subject leads one immediately to the possibility of radical surgery in its eradication, the obvious difficulty in knowing how far the process has extended greatly restricts surgery to the incision and drainage of localized collections of pus and to rare, selected cases in which either the immediate ligation of thrombosed veins or a quick hysterectomy for a uterus containing multiple abscesses might be seriously

considered. According to Williams the latter two surgical procedures were in his experience indicated only once in every few years.

Complications in Treatment of Burns.—Penberthy and Weller present eleven cases illustrating the result of what may be considered maltreatment of burn lesions. Each case has been selected to emphasize this factor, as evidenced by the application of improper or incomplete methods of treatment. Attention is called to the long periods of morbidity, the local and general conditions as presented at the time of admission, and the difficulty in obtaining a satisfactory end result by subsequent treatment. The fact that legal procedures have not been instituted is perhaps a matter of good fortune. Strict adherence to the accepted principles of treatment as proposed by Davidson and others will, the authors believe, in the majority of cases prevent the unfortunate occurrence of these all too common complications. Prompt application of local treatment, proper supportive measures, follow-up care and attention, together with the correction of deformities as indicated, offer a reasonable hope for success.

Acute Ulcer of Vulva with Disease of Skin and Oral Mucosa.—Talalov reports two cases of acute ulcer of the vulva associated with lesions on the skin and mucous membrane of the mouth. In the first case, a girl aged 16 suddenly had a chill, fever, pustular and papulopustular lesions on the skin, numerous ulcers typical of acute ulcer of the vulva on the genitalia and perineum, round the anus, in the inguinal creases and in the right axilla, and aphtha-like lesions on the mucosa of the mouth. The smears from the ulcers on the genitalia, in the armpit and in the oral mucosa, as well as the histologic sections of the ulcers from the armpit, showed *Bacillus crassus*. In the second case, a woman aged 28 had aphthous stomatitis and, in connection with the menses, extremely painful ulcers on the genitalia, one of which persisted for one and one-half years. Histologic investigation in the two cases revealed essentially similar pictures both in the ulcers of the armpit and in those of the genitalia. In both cases the changes were revealed chiefly in the region of blood vessels, round which the infiltrate was concentrated. In the first case the clinical symptoms were caused by the general *Bacillus crassus* infection, with metastases to the skin and mucous membranes; in the second, acute ulcer of the vulva was accompanied by aphthosis.

Tubercloid Reaction in Lymph Nodes.—Apparently normal, superficial nodes that were excised from fifty-five patients with carcinomas of the lower lip and breast were studied microscopically by Laymon and compared with regional nodes that were removed from sixteen patients with nonspecific infections and from seventy patients with early untreated syphilis. One inguinal node from a patient with a primary tuberculous ulcer of the ankle and forty-nine nodes from twenty-five patients with fatal visceral tuberculosis were also examined. The author appraises the reports of other investigators and surveys the results of his study. Epithelioid cells in lymph nodes, according to the studies of

Maximow on tissue culture, most likely originate from both reticular cells and lymphocytes. Giant cells, in turn, develop from epithelioid cells by fusion and amitotic division. The tubercloid reaction does not occur in normal nodes. No section showed evidences of this type of structure. The tubercloid reaction in the lymph nodes in the group of so-called non-specific infections is rare. Such histologic structure was not observed in the nodes that were removed from patients with acute pustular dermatitis, furunculosis, pyoderma and similar conditions. Specific tubercloid structure was illustrated by the observation of microscopic tuberculous lymphadenitis in three of twenty-five patients, who showed no gross manifestations of tuberculosis of the inguinal nodes. The inguinal node from the patient with a primary tuberculous ulcer of the ankle presented a definite tubercloid structure. The lymphadenitis in early syphilis presented definite tubercloid structures in approximately 15 to 25 per cent of the cases. In the group of seventy patients, 15.7 per cent were found to have a tubercloid structure in the nodes. No parallelism between the tubercloid reaction and the results with luotest or the Mantoux test could be shown. The exact significance of this reaction cannot be proved, owing to the long course of syphilis and the placing of all the patients on an equal basis by chemotherapy. The clinical course of the disease indicates that the tubercloid reaction is not a manifestation of precocious tertiarism or malignant syphilis. If a direct comparison of the reactivity of lymphoid tissue with that of the skin could be done, the tubercloid reaction might be considered an index to a higher degree of immunity than was possessed by patients who presented only banal inflammatory changes in the nodes. The tubercloid reaction in lymph nodes may be considered only as a particular response against an invader and it does not possess the immunologic significance that it has when present in the skin.

Acne Vulgaris in Adolescent Children.—Nichols states that if seen early acne vulgaris and its disfiguring after effects may be controlled in more than 80 per cent of adolescent children. The method that he recommends consists mainly of keeping the skin dry and rather chapped by the use of mild and later stronger soaps and lotio alba of increasing strength and concentration. If the scalp is oily, it should be washed every ten days with castile soap. The face and skin must be made dry looking, with a slightly chapped appearance, and kept that way all the time. The treatment should be continued until at least the age of 15. To keep the skin dry, the face is washed before going to bed with mild castile soap and fairly hot water; then well sopped for five minutes with lotio alba one-fourth strength, allowed to dry on the skin and remain over night, to be washed off in the morning. This treatment should be continued until the skin is dry and rather chapped. If at any time it gets too chapped, the lotio alba should be omitted for three days. As the skin gets used to this treatment, the strength of the soap and lotion should be increased. Patients who have a tendency toward acne are benefited by gradual exposure to the sun or artificial ultraviolet radiation. Foci of infection, constipation, unbalanced diet and general hygiene should receive attention. The author used this method of treatment in forty-seven children between the ages of 8 and 12. In thirty-seven cases, after from three months to four years of treatment, the acne is virtually unnoticeable and well under control. Five cases are much improved and five are moderately improved.

Relation of Antepartum Care to Maternal and Infant Mortality.—DeNormandie suggests that following a minute surgical, clinical, mental and menstrual history a complete physical examination must be made to establish what the patient's condition is at that time. A vaginal examination determines whether microscopic examination of a smear should be made. A speculum examination is most important to discover a marked erosion of the cervix, a possible polyp or rarely an early cancer. A Wassermann test should be made. The hemoglobin should never be omitted, otherwise the anemias of pregnancy cannot be discovered early and proper treatment instituted. The patient's diet, exercise, recreation and rest should be inquired into and supervised. As pregnancy goes on, the visits should be made regularly at least once a month for the first six months and then every three weeks, during the eighth month every two weeks, and the last month once every week or ten days. A creeping up of the diastolic pressure is a most important point to be observed. The urinary examination for albumin and sugar should be done. The weight must be

watched carefully. At each visit abdominal palpation and measurement of the fundus should be done and the observations should be recorded. Between the seventh and the eighth month a careful vaginal examination should be made to determine the relation of the size of the baby to the pelvis. By the last month of pregnancy the physician should make up his mind as to the probable method of delivery that will involve the least risk to the mother and the baby. As the patient progresses in her pregnancy, the appearance of bleeding should suggest a placenta praevia until it is definitely proved otherwise. The vaginal examination that is made between the seventh and eight months will in most cases rule out placenta praevia. It will not, however, rule out a low attached placenta. A separated placenta is an emergency. It is often impossible in rural districts for the physician to see his patients as often as necessary, and in such cases the well trained public health nurse, carefully supervised, can be of tremendous help. The author believes that intelligent supervision during pregnancy has a real bearing on the incidence of septicemia as a cause of maternal mortality. Infant mortality will be lowered unquestionably if the cases are carefully studied and the proper method of delivery carried out in each case. A further reason for unsatisfactory antepartum care is that the rank and file of patients have not been educated to the necessity for seeking such care early.

Complete External Pancreatic Fistula.—Garis and Merkel suggest that complete exclusion of pancreatic juice from the intestine with loss by external fistula produces a highly characteristic clinical syndrome consisting of striking anorexia, nausea, intermittent vomiting, steatorrhea, extreme exhaustion, anhydremia and emaciation, with lethal termination. A clinical example of this symptom complex is presented, corresponding in all important respects with the deleterious and fatal effects of complete pancreatic fistula in experimental animals. The necessity for totality of the fistula in producing the complete

syndrome is stressed, presupposing in every instance a complete obstruction of the duct of Wirsung and an absence or obstruction of accessory duct openings into the intestine; hence the rarity of the condition. It appears that partial or incomplete pancreatic fistula may in certain instances be associated with such symptoms as anorexia, weakness, loss of weight and steatorrhea. Concomitant biliary principle and absence of trypsin or erosive properties in the fistulous fluid may lead readily to errors in diagnosis. The question is raised as to whether the exclusion of pancreatic juice from the intestine in some types of complete obstructive jaundice may not be the major factor in the rapidly fatal outcome, as for example in carcinoma of the ampulla of Vater and carcinoma of the pancreas.

Dial-Urethane for Obstetric Analgesia.—Brown contends that by making the injections of dial-urethane slowly (about 1 cc. per minute) it is possible to adjust the dosage to the individual patient much more accurately than by a fixed volume dose, as used by Nelson. The patient is told that she will feel relaxed and sleepy from the injection; otherwise, alarm may be experienced over the peculiar sensation. The solution, 4 cc., is drawn up into a 5 cc. syringe and the needle is thrust through the wall of the vein. Injection is made slowly, the patient being constantly questioned, and the injection is discontinued when she no longer responds. In some cases 2 cc. of the solution will suffice; in others it may be necessary to inject the full 4 cc. The author has never given more than the latter amount in any single injection. If sound sleep does not occur between pains, a second injection of 2 cc. is given in thirty minutes. Further injections, each of 2 cc., may be given, but he has not exceeded a total of 8 cc. in the course of any labor. He has used the dial-urethane solution in fifty-six cases and he is convinced definitely that, used according to his method, it is the most satisfactory obstetric analgesic that he has ever employed.

Torsion of Fibromatous Uterus.—McIver and Buxton report a case of torsion of a fibromatous uterus occurring in a woman 62 years of age and producing acute symptoms and collapse. Preoperative treatment consisted of transfusion and intravenous dextrose infusions. A supravaginal hysterectomy was performed under local anesthesia, with recovery. Approximately 140 cases have been reported. In considering the pathology it is noted that the tumor responsible for the twist is usually large and may be single or multiple, sessile or pedunculated. The changes taking place in the uterus and fibroid depend on the extent to which the circulation is cut off and vary from edema and congestion to necrosis. The torsion usually takes place at the isthmus; the twist is commonly from left to right and may be through as few as 90 degrees or as many as 450. There are a number of etiologic factors that are not clear, though certain facts may be noted. Before the rotation occurs there is usually a thinning and stretching of the isthmus as the tumor increases in size, so that this structure forms a pedicle, which may be twisted readily. Asymmetry in the growth of the tumor may be a factor in the torsion; movements of the body may be important in initiating the twist. The cases fall into two clinical groups: one giving an acute, fulminating picture similar to that encountered in twists of an ovarian cyst or pedunculated fibroid, the second presenting mild symptoms, which sometimes continue over a period of years. Laparotomy is indicated in the acute group and probably in most of the chronic variety. In the acute group it is desirable that operation be carried out before secondary degenerative changes occur. In collapse, appropriate treatment should be carried out before operation. The type of operation selected depends on the pathologic condition found. Supravaginal hysterectomy is usually indicated, although at times a more conservative procedure, such as myomectomy, is the operation of choice.

*A Dosage System for Gamma Ray Therapy: Part I and Part II. R. Paterson and H. M. Parker.—p. 592.

Dosage System for Gamma Ray Therapy.—Paterson and Parker describe a practical system of dosage measurement, applicable to all forms of radium therapy other than certain types of interstitial implantation. The international roentgen unit is accepted as a satisfactory unit of quantity of gamma radiation, and the international millicurie hours (Imc. Hr.) of Sievert assessed as equal to 8.4 roentgens. Graphs are submitted showing the amount of radium required for various distances on any applicator to produce a dose of 1,000 roentgens over any desired area. A system of rules is also given, defining how, in the situations encountered in actual clinical practice, radium must be distributed on such applicators to produce a reasonably homogeneous radiation over the whole of a treated surface. The effects of certain dosages of gamma radiation on normal and malignant tissue are described. The lethal dose for squamous epithelioma appears to be 6,000 roentgens delivered as continuous radiation for a period of eight days; normal healthy skin tolerates safely the same dose delivered over a like period and normal mucosa tolerates considerably more than that. The physical and mathematical data on which the system is based are outlined.

Thyroidectomy in Congestive Heart Failure and Angina Pectoris.—Brenner and Donovan believe that any measure which promises to prolong in fair comfort the lives of patients with both the congestive and the anginal forms of heart failure, in whom the efficacy of all other forms of treatment has been exhausted, must command serious attention. The removal of the whole thyroid in patients without thyrotoxicosis, incapacitated by congestive or anginal heart failure, is not only comparatively safe but so greatly improves the patients' condition that many of them again become capable of work. They report six cases in which they performed total thyroidectomy. The patients stood the operation well. So far only two patients show signs of slight hypothyroidism. One

of the patients showing the obvious physical signs of hypothyroidism does not show the characteristic mental slowness. Some improvement in the circulatory symptoms occurred in all cases. One patient died of cerebral hemorrhage six weeks after the operation, but it seems improbable that her death was hastened by it. No patient is free from symptoms, but all are capable of more exertion. Some improvement occurred in both the congestive and the anginal symptoms, though previously the patients were steadily regressing in spite of all treatment. The cause of the improvement is not yet entirely beyond doubt. It seems probably that the main factor is the reduced metabolism. Levine pointed out that improvement sometimes occurred when there was no change in the metabolic rate, though the basal metabolic rate usually fell, with further improvement later. This was true in some of the authors' patients. Levine suggests that some of the improvement, especially in patients with angina, is due not to the diminished work of the heart but to humoral changes, particularly an alteration of the reaction of the heart to epinephrine. Though the diminished need of the tissues for blood containing oxygen after thyroidectomy is no doubt the chief factor in the improvement, Blumgart's observations on the velocity of the circulation must not be held to prove this.

Continuous Intravenous Infusion. E. L. Farquharson.—p. 530.

Adams-Stokes Attacks and Cheyne-Stokes Respiration.—Hill and MacKinnon present a case of auriculoventricular block in which the degree of the block varied from complete dissociation to simple prolongation of the PR interval; the ventricular complexes, however, were always typical of bundle-branch block, which varied from time to time in type (right and left). Histologic examination of the main stem of the bundle revealed no lesion. The authors attempt to explain the variations in the ventricular complexes and in the degree of dissociation on the basis of bilateral bundle-branch lesions. Adams-Stokes attacks were associated with disturbances of respiration, analysis of which was made from polygraph tracings of the pulse and respiratory movements. Short asystolic pauses were followed by apneic periods brought about apparently by the returning circulation, and, when Adams-Stokes attacks occurred in rapid succession, a form of Cheyne-Stokes respiration was produced. Longer asystolic periods were associated with a frankly asphyxial behavior of the respiration. The mode of the causation of these respiratory disturbances is discussed.

Lipoid Granulomatosis of Bones (Hand-Schüller-Christian Disease). J. S. Fraser.—p. 666.

Otosclerosis.—According to Gray, the essential causative factor of otosclerosis is a gradually increasing defect in the vasomotor mechanism which governs the nutrition of the structures of the organ of hearing as a whole. The axon reflexes are, of course, included in this vasomotor mechanism, and the stimulus which excites the vasomotor mechanism is sound and sound alone. Consequently the vestibular apparatus and the semicircular canals are unaffected. There is no evidence whatever of any defect in any of the endocrine glands or their

secretions in otosclerosis. Neither is there any evidence of any defect in the bone metabolism of the body. On the contrary the subjects of otosclerosis are, apart from their deafness, perfectly normal persons with ordinary average health. The deafness of otosclerosis bears little relationship to the extent of the disease in the bone. The deafness may be severe when the stapes is hardly fixed at all. The severity of the tinnitus bears no relationship at all to the extent of the disease in the bone. The extent of the change in the bone bears little relationship to the duration of the disease. The extent of the changes in the bone appears to depend on the age of onset of the disease. The earlier the time at which the otosclerosis begins, the more extensive will the bone lesion become. The deafness of otosclerosis is to a large extent functional and is the result of the insufficient supply of blood to all the nerve structures concerned in the perception of sound. The preponderance of women as subjects of otosclerosis is the result of the greater instability of their vasomotor system and the more frequent disturbances to which it is exposed. The changes in the bone show a remarkable bilateral symmetry, even to minute details. This symmetrical distribution is explained readily by the author's view of the causative factor of otosclerosis. The vasomotor nerves governing the nutrition of the organ of hearing are anatomically symmetrical like other nerve structures in the body. If, therefore, structural changes occur as a result of defective functioning of those nerves, such structural changes will be naturally bilaterally symmetrical in their distribution.

Rheumatoid Arthritis, with Especial Reference to Arthritis Clinic at Royal North Shore Hospital of Sydney. A. L. Ducker.—p. 347.

Cell Reactions in Lymph Nodes Draining Sites of Primary Carcinoma.—Welsh investigated the reactions of the lymph nodes draining the site of a primary carcinoma, the effects on the secondary lymph drainage of the primary carcinoma and the reactions of lymph nodes to stimuli which are not in any way cancerous. In comparing the reactions of the lymph nodes in the three types of lesion it is observed that in all three cases the lymph nodes show increased activity of both types of cell (lymphocyte and reticulo-endothelial). But whereas in the case of pyogenic infection there is an accumulation of polymorphonuclear cells both at the site of the lesion and in the blood and no increase of lymphocytes, in tuberculous and syphilitic lesions there is an increase of lymphocytes both at the site of the lesion and in the blood. In contrast to these two, a primary carcinoma may be found surrounded by lymphocytes, but there is no appreciable increase of lymphocytes in the blood. Nevertheless the activity stimulated in the lymph nodes draining the site of a primary carcinoma is a defensive reaction, though the exact mechanism of this reac-

tion is not known. The endothelial cells lining the sinuses of the lymph nodes become transformed into one form of monocyte and thence into the macrophage. The lymphocytes may also on occasion assume the form of macrophage. The macrophage may eventually take the form of fibroblasts. Therefore it is possible that the macrophages derived from both types of cell within the lymph nodes play some part in forming the fibroblastic defensive reaction at the site of the primary carcinoma, in addition to whatever defensive functions they perform within the lymph node. Lymphoid tissue is one of the most sensitive of normal tissues to radiation, especially when it is in a condition of hyperplasia and proliferation. As the immediate lymph nodes draining the site of a primary carcinoma show the greatest hyperplasia, it suggests that they are the chief source of the natural defense against the invading new growth, not only within their substance but also possibly at the primary lesion. If this is so, one should consider whether prophylactic radiation to these nodes could be applied in such a way as to get the maximal benefit without impairing their natural defensive functions.

Advances in Treatment of Blood Diseases.—Wits states that recent advances in the treatment of diseases of the blood have been effected by the introduction of new remedies and also by refinements or greater precision in the use of old remedies. Improvements in therapeutics have to a large extent been the consequence of improvements in diagnosis; e. g., the clinical resemblance between aplastic anemia and hemorrhagic purpura may sometimes be so close that they can be distinguished only by complete examination of the blood. Purpura haemorrhagica is relieved in the most striking manner by splenectomy, an operation that is not only useless but may be harmful in aplastic anemia. Disorders of blood formation are usually highly specific in etiology and response to treatment, and exact diagnosis must precede successful treatment. The author discusses the present place of the following in the treatment of disorders of the blood: iron, copper, x-rays, arsenic, phenylhydrazine, pentnucleotide, transfusions, splenectomy, and liver and stomach preparations.

Modern Methods in Orthopedic Surgery.—Jones points out that one of the most important advances in orthopedics has been the recognition of the inherent power of tissues to deal successfully with infection that is drained adequately. It has been shown that repair is delayed and not accelerated by frequent dressings and by the application of strong antiseptics. Antiseptics may devitalize organisms, but they also destroy healthy young cells, and, if to the tissue destruction of infection is added the tissue destruction of antiseptics, the volume of discharged pus is increased greatly and there is a corresponding increase in the degree of toxic absorption. Moreover, the daily removal of dressings for inspection of the wound is as useless and as harmful as the daily lifting of a bulb for inspection of its growth.

- *Problem of Cure of Tuberculous Meningitis in Nursing. P. Rueda.—p. 577.

Tuberculous Meningitis in Infants.—Rueda describes several cases of tuberculous meningitis in infants and considers the present state of clinical knowledge of the condition. He concludes that the ordinary hopeless outlook is not justified and that the cases of spontaneous recovery should be a considerable stimulus to the study of therapeutic cure. Careful restudy of the anatomopathologic and clinical processes is necessary, this having been delayed by the accepted but unjustified hopeless outlook. The cure of tuberculous meningitis probably depends on the early diagnosis. Minute study of the cerebrospinal fluid should open new horizons for the favorable modification of the prognosis of tuberculous meningitis. Finally, he believes it necessary to change the manner of considering the results obtained by analysis of the cerebrospinal fluid.

*Pathogenesis and Treatment of Proliferating and Stenosing Proctitis. J. Gatellier and A. Weiss.—p. 554.

Suprarenalectomy in Obliterative Arteritis.—Leibovici discusses the various aspects of suprarenalectomy in obliterative arteritis. The physiologic basis is uncertain. Technically there are several methods available, but in any case as much delicacy as in a neurosurgical operation should be used. Histologic examination is necessary to confirm the authenticity of the suprarenalectomy. He concludes that clinically—the only adequate basis at present—the operation does not seem to produce definite, lasting or general vasodilatation. It does not seem to have diminished the percentage of necessary amputations. In general the author feels that the results do not as a rule justify such a radical procedure.

Pathogenesis and Treatment of Proctitis.—The possible causative factors of proctitis are considered in detail by Gatellier and Weiss. They believe that proliferating and stenosing proctitis constitutes one of the clinical manifestations of a much more generalized condition characterized essentially by a lymphatic process capable of invading singly or simultaneously the different lymphatic systems of the perineum. They feel that in the majority of the cases this proadenolymphitis is due to the virus of inguinal lymphogranulomatosis (Nicholas Favre disease). Study of the histories of 139 cases of inflammatory stricture of the rectum treated by different surgical methods and followed for several years demonstrated the failure of these surgical extirpations, since recurrence was practically the rule. When the present theory of pathogenesis is considered, this failure of surgical treatment is not surprising. Palliative and medical treatment, or especially specific treatment of the causal disease, is to be preferred to surgery, but surgical treatment can still be used favorably in the completely inactive cases.

- *Physiologic and Pathologic Action of Liver in Diuresis. M. Villaret.—p. 1529.
Maintenance of Position of Fractures of Neck of Femur Without Arthrotomy. P. Brocq and R. Dulot.—p. 1532.
Transillumination in Diagnosis of Breast Tumors. R. Huguenin.—p. 1534.
*Barbituric Arthralgias and Myalgias. P. Castin and P. Gardien.—p. 1536.

Action of Liver in Diuresis.—As a result of experimental physiologic studies on the blocking action of the liver and portal circulation, Villaret concludes that the hepatic portal system plays a dominant part in the mechanical regulation of water exchanges. This regulatory action, instead of being simply passive as in the cases of vascular stasis, for example, with a pyelophlebitis or sclerosis of the liver, is also dependent on an active physiologic mechanism—that of the functioning

of the suprahepatic sphincter system. In the first instance the abnormal increases of volume of the circulating medium initiates the damming action of the liver. The second important part of the liver is a system of protection against heterogenous albumins. The intravenous injection of a liquid into a normal person causes less diuresis than oral administration, because of the reflex blockage caused in the liver by a massive increase in fluid. Practically, these views demonstrate the desirability of the therapeutic production of diuresis by fractional fluid injection in the decubitus position rather than massive fluid intake.

Barbituric Arthralgias and Myalgias.—Castin and Gardien report six cases in which joint or muscle pains developed in the course of barbiturate administration. The painful symptoms were unaccompanied by objective signs except for the discomfort connected with the pain. There were no sensory or vasomotor disturbances or abnormalities of the tendon reflexes of the affected limb. Only one patient showed atrophy of the right deltoid. Only one articulation was usually involved, but it seemed that its functional incapacity was due to the muscles which move it. These pains seemed to occur only after prolonged administration of the drug. No marked sexual distribution is apparent, and the age distribution appears to be simply in proportion to the frequency of use. The authors state that, as a general rule the barbituric algias are no more a contra-indication to the use of this drug than are the skin eruptions and other reported complications.

- Correct Diathermy in Sciatica. A. Keller and M. J. Purtschert.—p. 927.

Ischemic Contracture of Fingers Following Arm Fractures in Children.—According to Scherb, the ischemic contraction of the fingers develops in the following manner: Shortly after the injury (from six to eight hours), severe pains set in and radiate to the fingers. The hand and the bent fingers are bluish red or blue and edematous, and attempts at passive stretching of the fingers are extremely painful. After about two weeks, pains and the swelling subside, but a clawlike position of the fingers develops which is characteristic for ischemic contracture of the fingers, and, depending on the involvement of the peripheral nerves, sensory and trophic disturbances set in. However, the involvement of the nerves does not necessarily belong to the symptomatology of ischemic contracture, for the contraction is of a myogenous nature, in that the muscle tissue necrotizes as the result of a deficient blood supply and is replaced by cicatricial connective tissue. The opinions about the cause of ischemic contracture are still divided. Some assume that it is the result of the bending of the vessels and nerves on the edge of the fractured piece of bone or of an incarceration of the vessels; that is, of a circulatory disturbance at the site of the fracture. The author does not accept this theory but advances evidence indicating that ischemic contracture of the fingers is caused by the subfascial hematoma. The origin of the hematoma makes it understandable why only the flexor muscles of the lower arm become involved. The bandage is not responsible for the contracture, for if this were the case the extensor muscles would likewise become involved. The author thinks that, if the first symptoms of ischemic contracture are observed early, a lengthwise division of the fascia of the lower arm should be done in order to relieve the pressure of the hematoma on the threatened muscles. As treatment he recommends that stretching of the contracted flexors of the fingers should always be tried by conservative measures and states that only slow progress can be expected. If in case of a supracondylar fracture the flexors are completely destroyed, a substitute could eventually be produced by tendon transplantation.

Treatment of Anorexia in Children.—Bernheim-Karrer emphasizes that gastric disturbances are not given sufficient attention in the treatment of anorexia of small children. He thinks this the result of gastrogenic anorexia being frequently confused with neurogenic anorexia. A gastrogenic anorexia may become superimposed on a neurogenic form. Retardation in the evacuation of the stomach alone may lead to loss of appetite. He describes several cases of nurlings and small children. In nervous anorexia the tongue is usually clear; it was coated in the reported cases. Whenever the tongue is coated, a purely nervous origin of the anorexia must be doubted and it is advisable to examine the contents of the stomach. In nervous anorexia the examination of the stomach usually gives negative results or reveals only a slight motor insufficiency or hyperacidity and hypotonia. However, if gastritis exists, there are usually considerable digestive residues. In case of a pronounced hyperacidity, the administration of sodium bicarbonate is helpful. The gastric catarrh may be counteracted by irrigations with Vichy water, but care should be taken that the pressure is not too high, for this would increase the already existing hypotonia of the stomach. In one of the children the anamnesis revealed that the mother and grandmother had had gastric diseases and it is possible that here an organic deficiency was involved. The author stresses as the most important point the efficacy of gastric irrigations.

Bilateral Tubal Pregnancy.—Stahel reports the case of a woman, aged 36. Severe pains in the right hypogastrium with vomiting and constipation led to the diagnosis of appendicitis, but at first the patient did not consent to an operation. A sudden recurrence of the severe pains was diagnosed as perforation of the inflamed appendix or perhaps ruptured tubal pregnancy. The discharge of blood from the vagina and another examination led to the diagnosis of ruptured tubal pregnancy of the right side, and an operation was done at once. A tumor, the size of an apple, which ruptured when it was dislocated, was detected on the right side of the uterus, and the opening discharged blood, a fetus 5 cm. in length, and placental tissue. The right tube and ovary were removed but, in spite of careful hemostasis, bleeding continued. Further examination of the pelvic organs revealed that the left tube was torn, discharged blood and contained a fetus of approximately the same length as the right tube. The left tube was likewise removed but the ovary was left intact. Microscopic examination disclosed a bilateral chronic salpingitis and it may be assumed that this was the cause of the tubal pregnancy. It is possible that this salpingitis in turn was caused by an old gonorrheal infection. Since the two fetuses were approximately of the same size, it is probable that two ova were fertilized simultaneously. The woman recovered in a comparatively short time.

Clinica Medica Italiana, Milan

- Carcinosis of Skeleton Probably Due to Latent Pulmonary Neoplasia. G. Ferrari and G. E. Dolfini.—p. 915.
- *Size of Erythrocytes with Granulofilamentous Reaction in Relation to Physiologic and Pathologic Anisocytosis. G. Angelini.—p. 945.
- *Oxalemia and Oxaluria in Alterations of System Regulating Glycogen Metabolism. G. Battistini.—p. 971.
- Research on Venous Pressure of Limb Subjected to Pressure. G. Martini.—p. 982.
- Subarachnoid Hemorrhages. M. Dalla Palma.—p. 990.

The Size of Erythrocytes.—Angelini studied the size of the reticulocytes and the erythrocytes in normal conditions and in various diseases of the liver. He maintains that anisocytosis may be observed in the early stages of the erythrocyte formation (reticulocytes) in a manner corresponding to the anisocytosis commonly expressed by the erythrocytometric formula. The existence of this anisocytosis of immature cells must be kept in mind in interpreting anisocytosis in general. The reticulocytes offer a formula of larger measurements than the constituents of the general erythrocytometric formula; the smaller elements in the latter formula are not found in the reticulocytes, nor can it be stated that they are even young elements. The variety of the size of the erythrocytes must not be considered merely as an expression of the different phases of their life cycle (large young erythrocytes, small old erythrocytes). There is a sound basis for believing that in the course of their existence the erythrocytes, like other cells, undergo a

reduction in size. Only the extreme examples may be considered products of new formation (maximal erythrocytes) or on the other hand of senescence (minimal erythrocytes). In determining the size of the others, the author advises caution, especially in anisomicrocytosis (hemolytic anemia, infantile splenic anemia and pernicious anemia), in which relatively small forms are also found among the reticulocytes. A similar reduction is missing only in some cases of cirrhosis of the liver with a macrocytic appearance, in which the formula of the reticulocytes coincides with that of the erythrocytes in general.

Oxalemia and Oxaluria in Alterations of System Regulating Glycogen Metabolism.—Battistini determined the oxalic rate of the blood and the urine in various changes of the system regulating glycogen metabolism. All of twenty-four diabetic patients examined presented hyperoxalemia and hyperoxaluria, and the values amounted to two and three times the normal rate. The rate of oxalemia and oxaluria was higher in cases of so-called fat diabetes and less marked in forms of diabetes complicated by acidosis. The oxalemic curve after ingestion of dextrose remained elevated beyond the third hour. By eliminating the carbohydrates from the diet of patients presenting slight forms of diabetes and by administering insulin to patients presenting grave diabetic conditions, the author obtained a lowering of the oxalic rate of the blood and urine. He encountered a marked hyperoxalemia and a slight hyperglycemia in eight cases of atrophic cirrhosis in an advanced stage, in one case of syphilitic hepatitis and in one case of carcinoma of the liver. In these hepatic alterations, after administration of dextrose, the oxalemic curve remained elevated beyond the third hour as in the glycemic curve. The author states in conclusion that the oxalic metabolism is intimately connected with the carbohydrate metabolism, of which it is an intermediate product.

Pneumoperitoneum in Perforation of Gastric and Duodenal Ulcers.—Fernández Saralegui and Belleville emphasize the importance of the roentgen examination of the abdomen in acute abdominal conditions in patients with a positive Jobert's sign (disappearance of the hepatic dullness on percussion in the liver area). The sign indicates the presence of spontaneous pneumoperitoneum, the typical syndrome of perforation of a hollow viscus, and its roentgen verification indicates the emergency of an immediate surgical intervention on the patient. The chamber of air in spontaneous pneumoperitoneum following gastric or duodenal perforation shows itself in the roentgen picture as a limited semilunar space of uniform transparency, located between the diaphragm and the convex aspect of the liver, in the upper part of the subphrenic space. The roentgenogram of spontaneous pneumoperitoneum by ulcer perforation may be differentiated from similar roentgenograms, such as those given by spontaneous pneumothorax of the base of the lung and by pyogaseous subphrenic abscess and gaseous peritonitis, by the physical, functional, local and general symptoms, and from the roentgenogram of hepatodiaphragmatic interposition of the colon (Kausch's internal tympanism) by the differential roentgen characteristics of the latter, as described by Chilaidditi. Two cases of spontaneous pneumoperitoneum by perforation of ulcers of the anterior aspect of the pylorus, with atypical and classic clinical pictures, respectively, are reported. In both cases the results of the roentgen examination of the abdomen that confirmed the diagnosis of pneumoperitoneum, based on the presence of a positive Jobert's sign, were the basis for the decision to perform an immediate operation, which saved the life of the patients.

Postoperative Intravenous Injections of Sodium Chloride.—Berri confirms Robineau and Lévy's statements on the prophylactic value of the injections of hypertonic salt solution for the prevention of accidents accompanied by hyperazotemia and hypochloremia, as appeared in the *Presse médicale* 81:1563 (Oct. 11) 1933 (abstr. THE JOURNAL, Dec. 2, 1933, p. 1836). The technic is as follows: A subcutaneous injection of 500 cc. of isotonic dextrose solution is given to the patient in the course of the operation, followed, after awakening from the anesthetic, by an intravenous injection of 400 cc. of a 4 per cent hypertonic solution of sodium chloride. A second and then a third injection of 300 cc. each of a 4 per cent hypertonic solution of sodium chloride, controlled by the previous determination of the chlorides in the blood and in the urine of the patient, are given to him on the second and third days after the operation. The author obtained satisfactory results in three cases. One of the patients had renal insufficiency complicating the prostatic disease for which the operation was performed. In all cases the condition of the patients followed a favorable evolution: Hyperazotemia did not appear, the urinary secretion was practically normal with a nearly normal elimination of chlorides, the loss of weight was minimal, and there was an early elimination of gases during the first twenty-four or forty-eight hours after the operation by which intestinal and painful abdominal complications were prevented.

Dilatation of Calices of Renal Pelvis.—Salleras says that pyelography permits the differentiation of the painful nontuberculous form of dilatation of the calices of the renal pelvis from the painful tuberculous form, as well as the establishment of a diagnosis of the association of the two types of dilatation in one and the same kidney. The pyelogram, in cases of painful nontuberculous dilatation, shows the borders of the ends of the renal calices, in their site of papillary implantation, regular and well defined. The image of the kidney is clear. The dilatation is uniform in the main calices of the kidney so that the kidney appears in the pyelogram like the shadow of a clover leaf. The pyelogram in cases of painful tuberculous dilatation shows the presence of tuberculous ulceration, and the shadow of the kidney is blurred and uneven. The pyelogram in the associated form shows blurred spots at the site of tuberculous lesions and the typical clear aspect of nontuberculous dilatation at the nontuberculous areas. Two cases of the painful nontuberculous and the painful associated nontuberculous and tuberculous forms are reported. In both cases the study of the kidney, removed by nephrectomy, permitted the verification of the pyelographic diagnosis.

Pseudotumoral Form of Syphilis of Bones.—Satanowsky and Favergioti say that when a medical antisyphilitic treatment fails to improve bone lesions, which by their roentgen aspect and by the examination of the patient seem to be of syphilitic origin, it is advisable to resort to a different medical antisyphilitic treatment before deciding on the performance of a mutilating operation or even of an exploratory operation. They report the case of a syphilitic patient who had a negative Wassermann reaction and who was suffering from a pseudotumoral syphilis of the femur. A combined treatment consisting of intravenous injections of 0.02 Gm. of mercuric cyanide every other day, and oral administration of 5 Gm. of potassium iodide daily, resulted in a marked deterioration of the patient and in the appearance of a tumor at the site of the bone lesion, which on histologic examination of some fragments obtained during an exploratory operation proved to be a chronic inflammatory process of the muscular tissues with abundant proliferation of the connective tissues and hyaline degeneration of the muscular fibers. The process was interpreted by the authors as a propa-

gation of gummas from the syphilitic bone lesion, which invaded the surrounding tissues. The change of treatment to the administration of quinine-iodide-bismuthate injections, each injection containing 0.16 Gm. of bismuth and given every other week, resulted in the speedy disappearance of the tumor and a marked improvement of the general condition of the patient.

*Clinical Aspects of Ovarian Dysgerminoma. H. O. Kleine.—p. 89.

Porphyrin Elimination During Pregnancy.—Carrié and Herold studied the porphyrin elimination in healthy pregnant women by means of the spectrophotometric method. They found that toward the end of pregnancy there is a gradual decrease in the elimination of porphyrin. They explain the relations between the porphyrin metabolism and the blood pigment metabolism and are of the opinion that the reduction in the porphyrin elimination, in spite of the increase in the disintegration of erythrocytes at the end of pregnancy, is due to the fact that the hemoglobin derivatives (porphyrin) are largely taken up by the fetus to serve in the formation of blood.

Clinical Aspect of Ovarian Dysgerminomas.—Kleine reports the histories of seven patients with dysgerminoma. The patients were free from hermaphroditism, but they were of the hypoplastic asthenic type. Their ages varied between 15 and 24 and one was 30 years old. The author points out that the dysgerminoma is characteristic for young women. In five patients the dysgerminoma was unilateral, in one bilateral, and in one it was at first unilateral but, shortly after the one tumor had been removed, another one developed on the other side. Rapid growth seems to be a characteristic of this type of tumor. Histologic examination disclosed in all cases the typical picture of the solid, large cell, round-cell carcinoma, the growth of which was either alveolar or strand-like. The author compares the hormone reactions of the three types of blastomas of the female gonad, of the granulosa blastomas, arrhenoblastomas and dysgerminomas. The Aschheim-Zondek reaction is negative in all three types, but the folliculin reaction (estrus reaction) is positive in granulosa blastoma but negative in the two other types. The testicular hormone reaction is doubtful in all cases, but it may be positive in some cases of arrhenoblastoma and negative in the other two types. One of the patients observed by the author had a normal delivery before the operation, and another patient gave birth to two normal children following the removal of the left ovary on account of a dysgerminoma, the size of a child's head. This proves that the healthy ovary of a woman with dysgerminoma may retain its function. But, on the other hand, one of the patients died as the result of a rapidly growing dysgerminoma of the left ovary, six months after a dysgerminoma had been removed from the right ovary. Three patients have remained healthy after the removal of the dysgerminoma for periods of seven, sixteen and twenty-four years respectively.

Clinical Experience with Links' Early Diagnosis of Carcinoma.—Weber and Schüle report their results with Links' serum diagnosis of carcinoma in 100 clinical cases. Blood is drawn from the cubital vein into a receptacle so arranged that each stage of coagulation can be separated, yielding three serum fractions instead of one. The three specimens are subjected

to a chemical analysis consisting of the determination of the number of cations utilizing the potassium and magnesium content of the serum. The three fractions are placed in receptacles and are treated by heat so as to rid them of all organic particles. The resultant clear fluid is examined for its potassium content by titration and for magnesium by a colorimetric micromethod. It is not the total of the six figures obtained but the relationship of the total to the erythrocyte count that determines whether the test is positive or negative. The authors do not furnish further details except to state that figures above 100 are considered a positive test, while those below are considered negative. The test was positive in the forty-one cases of definitely established carcinoma. In a control group of forty-two cases that were definitely not carcinoma, five gave a figure above 100, in other words were positive. This gives 88.1 per cent of correct results and 11.9 of errors. In a third group of eleven suspected cases of malignancy, the test proved to be correct in seven, probably correct in two, and undetermined in two. The authors feel that the small number of cases tested does not allow any conclusions regarding its specificity. It appeared significant, however, that all the sarcoma cases gave a negative result suggesting a specific response of the part of the epithelial tumors.

Sterilization Operations.—In discussing the new law for prevention of hereditary diseases, Fromme states that the German law makers regard sterilization performed for purely social indications as a mutilation subject to severe punishment. Because the operation in man is easy to perform, the law specifies that it may be done in specified institutions only, and by appointed surgeons. Thus far no legislation exists permitting the marriage of a normal person with one congenitally abnormal but sterilized. The author warns that the operation of sterilization may be needlessly performed in cases of azoospermia and cryptorchism. The term vasoresection recommended by Haberland was given legal acceptance. The question of how soon after vasoresection the person is rendered sterile has not been settled. Spermatozoa may remain alive in the seminal vesicles and in the efferent ducts for a long time. The question of the length of quarantine after vasoresection is bound up with the solution of this question. No profound hormone disturbance is to be feared, because spermatogenesis, while temporarily diminished as the result of stasis, soon recovers and may continue for a number of years. That the patency of the duct can be restored by an operation was demonstrated by Monaco in animal experiments. It would therefore be possible for a sterilized person to circumvent the law by having a restoring operation performed outside of Germany. The author is inclined to minimize the effect on the libido in the sense of a Steinach operation after a bilateral vasoresection. In discussing castration the author calls attention to two interesting phenomena recently pointed out by Lange in his observations on 310 castrated men; namely, the development of gynecomastia in thirty-two and an increase in height of more than 2 cm. in persons past the physiologic age of growth. The author is of the opinion that castration will fail in a high percentage of cases to cure the sexual aberration for which it is performed. Not only does the libido as well as potency frequently persist after castration, but it is evident that the libido is grounded at least as much in the psychology of the person as it is in his testicles.

Influence of Diathermy on Blood Perfusion of Brain.—Frey and Schneider give a theoretical explanation as to why, in diathermy of the skull, the temperature of the brain can be

elevated only slightly. They demonstrate this fact in experiments on dogs, which revealed that the diathermic heating of a portion of the brain of a living dog amounts to only from 2 to 10 per cent of that of the musculature. However, diathermy of the skull effects a dilatation not only of the vessels of the skin and the muscles but also of the cerebral vessels. This dilatation of the cerebral vessels may be induced by applying diathermy merely to the facial portion of the skull, and, if this is done, the slightest heating of the brain is avoided. The diathermic dilatation of the cerebral vessels is thus not to be explained as a heat action but is doubtlessly due to reflex action. The authors think that the elicitation of the meningeal reflex described by the Schneiders is the important factor.

Takata Reaction and Pregnancy Toxicoses.—Since the Takata reaction is positive in certain hepatic disorders, particularly cirrhoses of the liver, and since pregnancy toxicoses are accompanied by various symptoms of a disturbed hepatic function, Neuweiler determined the outcome of the Takata reaction in the severe toxicoses of pregnancy. He employed the technic described by Jezler. The reaction was negative in healthy pregnant women, in five women with uncomplicated pregnancy kidney, in nine with threatening eclampsia and in six with manifest eclampsia. Even in the severest cases of eclampsia, which ended fatally and in which the histologic examination disclosed severe changes of the liver, the Takata reaction was negative. Five women with severe toxic hyperemesis, in three of whom abortion had to be performed because of severe hepatic disturbances, likewise had a negative Takata reaction. The author made control tests on patients with cirrhosis of the liver and always obtained a positive Takata reaction. He concludes that in pregnancy toxicoses the Takata reaction has no value as a functional test of the liver.

Duodenal Diverticulum and Pancreatitis.—On the basis of seventeen case histories, Frentzel-Beyme explains the connections between duodenal diverticulum and pancreatitis. The characteristic pain on the left side or in the back, the pancreatic stool and the increased or greatly fluctuating diastase values are the most significant of the symptoms indicating pancreatic involvement. Increased blood sugar content and the enlargement of the space of the head of the pancreas may indicate pancreatic involvement, but they are frequently absent. At any rate, a negative roentgenologic examination does not definitely exclude impairment of the pancreas. The author thinks that his observation that in extensive destruction of the pancreas there is usually a gastric subacidity requires further investigations on a larger material. In case of duodenal diverticulum there exist nearly always atypical intestinal disorders (heartburn, nausea, vomiting and a sensation of pressure in the gastric region). If the pancreas is involved from the beginning, which is the case when the duodenal diverticulum is located at the duodenal papilla, typical pancreatic symptoms are generally disclosed by the anamnesis. In these cases the course is usually rather severe and there is danger of acute necrosis of the pancreas. The duodenal diverticulum causes disturbances only when it retains substances and subsequently becomes inflamed. This is the case when the pedicle connecting the duodenal canal with the diverticulum is rather narrow. If the pancreas is in the normal position, it becomes involved in the disturbances only if the diverticulum is on the concave side of the duodenum. The clinical manifestations vary greatly in duodenal diverticulum and the diagnosis requires considerable study.

Descendants of Diabetic Patients.—Edelmänn observed that in women descending from families in which there is diabetes mellitus the extremities, particularly the lower ones,

are extremely slender. This slenderness is especially noticeable immediately above the ankle and the wrist. Moreover, the curvatures resulting from the bellies of the muscles, which are noticeable in normal persons, are generally lacking in these descendants of diabetic families. The author found also that the history of diabetes was usually in the paternal branch of the family. Thus it appears that the hereditary transmission of these characteristics goes through the father and is passed on to the female sex. But the author observed also a number of men with thin and weak lower extremities in whom the ancestry was diabetic. Persons with these characteristics do not necessarily contract diabetes, but those in whom there exists a considerable disproportion between the extremities and the trunk (adiposity of abdomen, hips and breasts) seem to have a predisposition for diabetes mellitus. The author inquired also about the ancestry of persons with extremely plump lower extremities and found that in these cases there was a history of diabetes mellitus in the maternal branch of the family. However, the latter material was comparatively small and further observation will be necessary.

Large Urinary Calculus in Child. G. Freund.—p. 1334.

Typhoid-Like Symptoms in Diseases of Blood.—Klima and Rosegger describe two cases of hemorrhagic aleukia and one case of acute lymphatic leukemia in which typhoid-like symptoms appeared. After the symptoms of the blood disorders had existed for a time and the patients had been treated for blood disease, there developed metcormism, abdominal pains (colics), tar stools and fever. All three cases terminated in death and the necropsies revealed intestinal ulcerations. Following a review of the literature, the authors stress that they do not deny that hemorrhagic typhoid is possible, for they are aware of the fact that thrombopenia is almost a typical symptom of abdominal typhoid and that some authors have observed a certain parallelism between the seriousness of the typhoid and the hemorrhagic symptoms. However, they think that the cases reported here are a proof that the reverse may be the case; namely, that typhoid-like symptoms may develop in malignant thrombopenia or in hemorrhagic aleukia.

*Significance of Overextension of Muscles in Paralysis. P. von Puky.—p. 1505.

Otitides of Nurslings.—Litschkus, after calling attention to the high incidence of otitides in nurslings, points out that these processes remain frequently undiagnosed. He thinks that the ears of a nursling should be examined whenever there is fever and the cause of this fever cannot be determined. In intestinal disturbances that are not caused by faulty nutrition, otoscopy is absolutely necessary. The author thinks that there is a connection between intestinal intoxication of nonalimentary origin and the suppurating processes of the middle ear and that in the majority of these cases the process of the ear is the primary disorder. He stresses that every pediatrician should master the technic of otoscopy.

Overextension of Muscles in Paralysis.—According to von Puky, extensive muscular paralysis may completely disappear after the acute stage of anterior poliomyelitis. In nearly all cases, at least some of the paralyzed muscles regain their function during the stage of reparation; that is, from one to two years after the acute stage. All muscles of the spinal nerve ganglion that have not been destroyed by the infection but have lost their function merely as the result of the pressure
